SUBSECT. 1.—*Chemical Principles and General Properties.*

1951. *Cheese is the curd formed from milk by artificial coagulation, pressed and dried for use.* In treating of milk, we have stated that curd, called also casein and *caseous matter*, or the basis of cheese, exists in the milk, and not in the cream, and requires only to be separated by coagulation. The coagulation, however, supposes some alteration of the curd. By means of the substance employed to coagulate it, it is rendered insoluble in water. When the curd is freed from the whey, kneaded, and pressed, to expel *it entirely*, it becomes cheese. This assumes a degree of transparency, and possesses many of the properties of coagulated albumen. If it be well dried, it does not change by exposure to the air; but if it contain moisture, it soon putrefies. It therefore requires some salt to preserve it, and this acts, likewise, as a kind of seasoning.

1952. *All our cheese is coloured more or less*, except that made from skimmed milk. The colouring substances employed are arnotto, turmeric, or marigold, all perfectly harmless, unless they are adulterated; and it is said that arnotto sometimes contains red-lead.

1953. *Cheese requires to be kept* in a dry room where there is a circulation of air, and they should be turned frequently. The room should be kept very clean by sweeping, to prevent the access of mites (*Acarus domesticus*) and other insects. The fly called *Musca putris* deposites its eggs in cheese, which afterward become the maggots called hoppers, or jumpers. Even the common bug will infest cheese if placed near where they resort. The production of mites may be checked by pouring spirits into the affected parts.

1954. *Some prefer cheese when it begins to change blue*, or begins to putrefy; and means are sometimes taken to produce this change, or render it *ripe*, as it is called. This is effected by putting the cheese into a damp place, and turning them from time to time. By this they absorb water, increase in bulk, become unctuous and soft, and begin to give out a peculiar smell, which increases until it becomes ammoniacal. Some gourmands, instead of allowing them to absorb water, saturate them with port wine or strong ale. The blue mould that appears upon the surface of cheese that has been cut and kept shut up too close is a species of fungus, or minute vegetable, and may be distinctly seen when examined by a magnifying glass; but the blue mould which appears in the interior of cheese is a substance not well understood.

1955. *Cheese, when analyzed*, is found to consist of carbon, 59·781; hydrogen, 7·429; oxygen, 11·409; nitrogen, 21·381. From its containing so large a quantity of nitrogen, it must be considered as a highly animalized substance.

1956. *As diet* for persons in sound health, and who have plenty of exercise, it appears to be salutary; but to those of weak constitutions, and valetudinarians, it is sometimes found difficult of digestion, particularly what is made of skimmed milk and much dried. Vauquelin has shown that cheese contains ammonia, particularly old cheese, and the odour of ammonia is very evident in what is decayed. It is probably the presence of this alkali that causes old cheese to prevent the injurious effects of acid fruits, as well as to render their taste milder. The fatness of cheese cannot be ascertained by its appearance: toasting shows this quality best. Some cheese, apparently fat, dry up with the heat, while some apparently dry cheese, when toasted, become fat. Cheese requires a certain time to acquire its proper flavour. When too new, it is insipid and wasteful.

1957. *Cheese varies in quality and richness* according to the materials of which it is made. It is made, 1, of entire milk, as in Cheshire; 2, of milk and cream, as at Stilton; 3, of new milk mixed with skimmed milk, as in Gloucestershire; 4, of skimmed milk only, as in Suffolk, Holland, and Italy.

When new milk or cream is employed partially, there is a good deal of fat or butter in the cheese, as in the Cheshire, Stilton, and Gloucester, whereas skimmed-milk cheese contains very little fat; but it is admitted by good judges that the quality of cheese depends as much, at least, upon the mode of manufacture as on the materials. Some of the most agreeably-tasted cheese is made of skimmed milk, as the Parmesan, and some of the Dutch cheese. Rich or fat cheese is prone to decomposition, and is apt to collect mites or maggots: hence the poor cheeses, such as the Dutch, are preferred for carrying to sea, from their keeping better. Braconnot has shown that the flavour of cheese depends upon a peculiar principle, which he has called *caseic acid*. For the process of making cheese, see Book XXV., "Dairy."

Subsect. 2.—*Varieties of Cheese.*

The principal varieties of cheese used in England are the following:

1958. *Cheshire cheese.*—This cheese is famous all over Europe for its rich quality and fine, piquant flavour. It is made of entire new milk, the cream not being taken off. The cheeses are generally of very large size, usually about sixty pounds' weight, and some have been made of one, or even two hundred weight. Each cheese is usually made of the produce of one day's milking from herds of from 100 to 200 cows, who feed in rich pastures on some of the finest land in England. Their excellence must be attributed to the goodness of the milk, their size and age, and the skill employed in the manufacture. The colour is not entirely natural; but a yellow tint is given by *arnotto*, marigolds, or carrots. It is said that some increase the richness and mellowness of the cheese by adding beef suet, or any other wholesome and sweet fat well clarified, which is poured into and mixed with the curd.

1959. *Gloucester cheese* is much milder in its taste than the Cheshire. There are two kinds of Gloucester cheese, single and double. *Single Gloucester* is made of skimmed milk, or of the milk deprived of half the cream; of course it is not very rich, but is often of good flavour. *Double Gloucester* is a cheese that pleases almost every palate: it is made of the whole milk and cream, and is a fat cheese, usually the kind employed for toasting, though the single often toasts very well. These cheeses are made of various sizes, the single generally eight to the cwt., and very thin, and the double four to the cwt., and at least twice as thick. As the two kinds sometimes resemble each other considerably, some honest farmers stamp a figure of a heart upon the single Gloucester, to distinguish it from the double. The true characteristics of Gloucester cheese consist in its great richness, together with the mildness of its flavour, and that smooth, waxy texture which makes it cut, even in thin slices, without crumbling, as Cheshire cheese is apt to do. Its oily matter is retained in toasting, by softening without being burned.

1960. *Stilton cheese.*—This, from its peculiar richness and flavour, has been called the Parmesan of England. Its name is derived from having been first made at Stilton in Leicestershire, though it is now manufactured very generally throughout the counties of Cambridge, Huntingdon, Rutland, and Northampton. It is made by adding the cream of one day to the entire milk of the next. The cheeses are all of a small size, from six to eight pounds' weight, and are of a cylindrical form, made in a deep vat, and are not considered to be sufficiently mellow until they are two years old, nor ripe until they exhibit spots of blue in the interior, marking the commencement of decay. It is said that some keep them in warm, damp cellars to accelerate the ripening. The blue part is of a peculiar nature, different, it is said, from the common blue mould of cheese. The decay should not be advanced beyond a certain point. A variety of Stilton, but not so rich, or of so fine a flavour as the last, is made in a net, and of the form of a pine cone, the net impressing lines on its surface.

1961. *Cottenham cheese,* made near a town of that name in Cambridgeshire, is a thicker kind of cream cheese than Stilton. Its superior delicacy and flavour are attributed to the fragrant herbage on the commons where the cows are pastured.

1962. *Sage cheese,* called also green cheese, is made chiefly in the vales of Gloucester and Wiltshire, by colouring some curd with bruised sage, marigold leaves, and parsley, and mixing this with some uncoloured curd; the whole is then made into a cheese, which, of course, exhibits a mottled appearance.

Among the Romans it was a practice to flavour cheese with thyme and other sweet herbs; and this custom was continued during the middle ages. We are told that the Emperor Charlemagne, arriving at a bishop's palace on a fast day, could get nothing but bread and cheese. The prelate, observing the king picking out with his knife small specks, which he mistook for impurities in the cheese, informed his guest that they were parsley seeds. The monarch tasted them, and liked them so much that he requested the prelate to send him an annual supply of cheese prepared in this manner.

1963. *Chedder cheese* is not exclusively made at the village of Chedder, in the Mendip Hills, Somersetshire. A great deal of the same kind is also made round Bridgewater, and in the marshes round Glastonbury. The cheese is peculiar, much resembling Parmesan; it has a very agreeable taste and flavour, and has a spongy appearance, the eyes being filled with a limpid and rich, but not rancid oil. The cheeses are generally large. But little of the prime Chedder cheese is made, that generally sold for it not being genuine, and is inferior.

1964. *Brickbat cheese.*—There is nothing remarkable in this except its form. It is made by turning with rennet a mixture of cream and new milk. The curd is put into a wooden vessel the shape of a brick, and is then pressed and dried in the usual way. It is best made in September, and is ready in six months.

1965. *Dunlop cheese* is famous in Scotland: it is so called from the Parish of Dunlop, in Ayrshire, where it was first or best made, and where the pastures are very rich; but it is now manufactured in other parts of Ayrshire. The best is made entirely from new milk, and it has a peculiarly mild and rich taste; but there is nothing remarkable in the manner of making it.

In some parts of England they never churn the milk, but only the cream; consequently they make little butter-milk, because the servants will not eat this, though they have no objection to skimmed milk. In Scotland and Ireland, on the contrary, they churn all the milk, and have, of course, much butter-milk, which is much relished there.

In the Highlands of Scotland they make a cheese for the table of a very high *gout*, an almost Tartarian preparation, by allowing the milk to become sour, and to coagulate of itself, which gives a flavour even more pungent than that of goat's-milk cheese.

1966. What is called in London *new cheese* is made chiefly in Lincolnshire, and is either made all of cream, or, like the Stilton, by adding the cream of one day's milking to the milk that comes immediately from the cow: they are extremely thin, and are compressed gently two or three times, turned for a few days, and then sent to be disposed of to be eaten new with radishes, salad, &c. It may be made in the following manner: Warm some cream, add rennet in the proportion of a spoonful to a pint, or more if necessary. Put the curd into a sieve, having a cloth at the bottom; when it has remained twenty-four hours, transfer it to a cheese vat, and cover it with a wet cloth and board; in about two hours it may be used.

1967. *Skimmed-milk cheese.*—Cheese made from the curd of skimmed milk, when all the cream has been separated, has in it no butyraceous matter, but is the caseous substance in a pure state, resembling very nearly white of eggs or albumen, or, perhaps, more nearly the gluten of wheat. This cheese from skimmed milk only is made in those districts of England where butter is the chief object of the dairy-man, as in Essex and Suffolk. What is made in England of this kind has scarcely any flavour, and dries almost as hard as horn, but is as digestible as the softer cheese, though not very palatable. It is, however, useful as part of ship stores, being less liable to spoil on a sea voyage than richer cheese, particularly in a warm climate. On the subjec of skimmed-milk cheese Dr. Anderson, celebrated for his writings on agriculture, observes that it is an erroneous idea to suppose that the agreeable taste of cheese depends solely upon the quantity of oily or fat matter it may contain. Parmesan cheese is made of skimmed milk; so are the Dutch cheeses, which many consider as very pleasant tasted. He has seen cheese made of skimmed milk that ate exactly like the finest cream cheese, and he considers that what is called richness in cheese depends as much upon the particular mode in which they are manufactured as upon the materials of which the cheese consists. In confirmation of this opinion, he remarks that, though the taste of double Gloucester differs so much from Cheshire cheese, yet they are both made from the same kind of milk.

1968. *Parmesan cheese.*—This most celebrated of all cheese is made in the duchy of Parma and Piacenza, and in various parts of Lombardy: at present the district of Lodi is in high repute for it. It was formerly supposed to be made from goats' milk; but it is made merely of skimmed cows' milk, and the high flavour which it has is supposed by some to be owing to the rich herbage of the meadows of the Po, where the cows are pastured, and by others solely to the process by which it is manufactured, a particular account of which may be seen in Cadell's "Journey in Italy, 1818." Half the milk has stood sixteen or seventeen hours, and the other half has stood only six. The milk is heated and coagulated in a caldron, and, without being taken out of the caldron, the curd is broken very small by an implement consisting of a stick with cross wires; it is again heated, or, rather, scalded, till the curd, now a deposition from the whey, has attained a considerable degree of firmness; it is then taken out, drained, salted, and pressed, and in forty days it is fit to put into the cheese loft. The best Parmesan is kept for three or four years, and none is carried to market till it is at least six months old. Another account of the manner of making it is to be found in the seventh volume of the Bath Society's papers, and in the second volume of Mr. Arthur Young's "Travels in France."

1969. *Dutch cheese.*—In Holland they coagulate their milk with muriatic acid instead of rennet, which occasions that pungent taste peculiar to this cheese, and preserves it from mites. The *Gonda* is most celebrated, which is made with extraordinary care. A detailed description of the mode of making it is published in the *Jour. Agri. des Pays Bas*, and is quoted in the excellent work by Margaret Dodds. The best Dutch cheese is made in the environs of Leyden, at Eidam and Friezland, where also a very large quantity is manufactured for England, of skimmed milk, chiefly for sea stores. In the Texel they make cheese from ewes' milk: a good deal of Dutch cheese of a round form comes now to London; it is of a low price, and frequently of very good quality.

1970. *Swiss cheese.*—Switzerland has been long celebrated for its cheese: several varieties of cheese are produced there, and though made of skimmed milk, or partially skimmed milk, yet are they remarkable for their fine flavour, which is partly owing to the herbage of the mountain pastures. That denominated from *Gruyère*, a bailiwick in the canton of Fribourg, is best known in England. This is flavoured by the dried herb of *Melilotos officinalis* in powder. The cheeses weigh from forty to sixty pounds each, and require to be kept in a damp place, and washed frequently with white wine to preserve it from the depredations of insects. Until of late, the manufacture of this cheese was limited to a few wealthy persons: as it is necessary for its quality that the cheese should be very large, and that the milk should be coagulated on the day it was taken from the cow, it was only by keeping a large number of cows that the manufacture could be carried on, and the owner of a few cows only was unable to succeed. At present, how ever, it appears that cheese dairies have been established by the poor peasantry joining together, and thus competing with the more wealthy. Another excellent cheese is made at *Neufchatel.* The *Schabziegar* cheese is made by the mountaineers of the canton of Glarus. It has a marbled appearance and aromatic flavour, from the bruised leaves of the melilot. The milk is exposed to the temperature of 46° for five or six days, when the cream is completely formed, and is taken off. The skimmed milk is coagulated by sour milk, and not by rennet, and the curd thus obtained is pressed strongly in bags, and when sufficiently pressed and dried, it is ground to powder, salted, and mixed with the bruised flowers or seeds of the Melilotos officinalis, and afterward again pressed into cheese. The entire separation of the cream, or unctuous part of the milk, is essential. Some Swiss cheese is also manufactured from a mixture of ewe-milk with that of the cow.

1971. *Westphalia cheese* is a skimmed-milk cheese, and is a remarkable instance of how much the quality of cheese depends upon the manufacture. It is described by some as being preferable to the Dutch, Swiss, and even Parmesan cheese. The cream is allowed to remain till the milk beneath is sub-acid; it is then removed, and the milk placed near a fire to coagulate. The whey is next expressed from the curd, which is dried and crumbled between the hands. It remains for several days until the putrid fermentation commences; but this is stopped by kneading it into balls with carroways, salt, butter, pounded pepper, and cloves. Sometimes these balls, or little cheeses, are hung up in the smoke of a wood fire.

1972. *Cheese from milk and potatoes* is manufactured in Thuringia and Saxony. The best potatoes are half dressed in steam, peeled, and reduced to a pulp. Five pounds of this are mixed with from one to ten pounds of sweet curd, and kneaded together, some salt being added; after lying for a few days, this is again kneaded, and then pressed into little baskets, where the superfluous moisture drains off; the cheese are then formed into balls and dried in the shade. These cheeses keep well in the dry, and their quality improves with age, with the advantage that they generate no vermin; their taste is said to exceed the best cheese made in Holland.

1973. *Cream cheese*, although so called, is not properly cheese, but is nothing more than cream dried sufficiently to be cut with a knife. To make it, a quantity of good sweet cream is put into a cheese vat, with green rushes sewed together on purpose, at the bottom of the vat, which must have a sufficient number of holes to let the whey which drains off pass freely away. On the top of this cheese are likewise laid rushes or long grass of the Indian corn, in the same manner as at the bottom, in order to allow it to be turned without being handled. It is usual to make these cheeses from one inch to one inch and a half in thickness. The thinner they are made, the sooner they are ready. It is kept in a warm place to sweat and ripen; but extremes of heat or cold are injurious, and some judgment must be used in managing it.

CHAPTER V.

BIRDS.

Sect. I.—INTRODUCTORY OBSERVATIONS.

1974. *The feathered tribe of animals*, or *birds*, furnish a considerable and varied supply of sustenance to man; and they possess this quality in common with quadrupeds, that none of them are absolutely deleterious when used as food, although their properties in this respect vary considerably. Like quadrupeds, also, some birds which have been found the fittest for the table have been long domesticated, while others remain always wild. Birds of prey are never eaten among us, their flesh being coarse, tough, and ill-flavoured.

1975. *Those which serve us as food may be divided into such* as are domesticated, as the common fowl, turkey, duck, and goose; wild birds, usually termed game, as the pheasant, partridge, grouse, woodcock, &c.; and some other wild birds, that are not considered as game, such as lark, pigeon, &c.

Of birds, both domestic and wild, some are white-fleshed, as the common fowl, turkey, and pheasant; others have a dark-coloured flesh, as the duck, goose, and pigeon, also grouse, blackcock, &c.

Game, in this country, is usually considered as a luxury rather than a general article of food; and it is frequently kept for some time, until it has acquired a peculiar odour, called *fumet*, and a certain slightly aromatic bitter taste.

Of aquatic birds, both swimmers and waders, many are very delicate, though in general they are disposed to become fat, and some have a rank, fishy taste.

1976. *Not only the fattening, but the flavour of birds* is very much influenced by the nature of their food. Those which feed upon grains and vegetables, as the common fowl, turkey, and pheasant, are the most delicate, and have the whitest flesh. Those which live partly on animal and partly on vegetable food, as ducks and geese, are brown-fleshed, and higher flavoured; and those which, being aquatic, live wholly on fish, have a taste savouring of the creatures they feed upon; it is remarked that the same bird may be made to acquire, in a certain degree, a peculiar flavour by managing its food accordingly. If permitted to go at large, with plenty of food, and under favourable circumstances, as in the case of common fowl in a farm-yard, they often get sufficiently fat; but domestic fowls are generally fattened for the market, and sometimes not in the way best calculated to promote their health, and, consequently, wholesomeness as food. Some wild birds are migratory, and can only be had while they remain with us; before the use of gunpowder these were caught by hawks trained for the purpose, a mode of killing calculated to render the flesh more tender; at present they are shot, hawking having gone out of use. Some small birds, as larks, are caught in nets and traps.

1977. *The fat of birds is not dispersed through the muscles or marbled, as it is in quadrupeds*; and different parts of the same bird differ very much in flavour and other properties. Every one knows how much whiter the pectoral muscles which move the wings are, when cooked, than those which move the legs; but the flesh of the latter is more juicy, and, when tender, from being young and well dressed, is by many preferred. The legs of the snipe and the woodcock are always preferred to the breast. The legs of birds are more apt to get tough and stringy when old, particularly the tendons and ligaments; hence the greater difficulty in carving them. The flesh of birds, particularly poultry, is extremely nutritious and easy of digestion; therefore very fit for valetudinarians.

1978. *The internal organs or viscera of birds* are partly eaten; of these the gizzard is digested slowly, and is not proper for dyspeptic persons. The intestines of the wood cock, called the *trail*, when dressed is considered by epicures as a delicate morsel. The liver has a peculiar flavour, from the bile contained in it: by some it is relished, and disliked by others. The livers of geese fattened and enormously enlarged, so much the fashion in some parts of the Continent, are really in a state of disease; and Dr. Prout remarks that it can scarcely be considered as free from danger to eat them.

1979. *The term poultry* is applied to all kinds of domestic fowls brought up in a farm-yard. In Britain, where much butcher's meat is consumed, these are generally esteemed a luxury, and, consequently, are not reared in such considerable quantities as in

France, Egypt, and some other countries, where it is used more as a common article of food. In France, poultry forms an important part of the live stock of the farmer, and it has been said of that country that the poultry-yards supply a much greater quantity of food to the gentleman, the wealthy tradesman, and the substantial farmer, than the shambles. It is well known that in Egypt it has been, from time immemorial, a considerable branch of rural economy to raise domestic poultry for sale, hatched in ovens, by artificial heat. The warmer climates are far more favourable than ours for the purpose of raising poultry; and the same remark necessarily holds with respect to this country, where the warmest and driest soils are best adapted to this production, more especially of chickens and turkeys.

It is conceived that the consolidations of farms, among other consequences, has diminished the quantity of poultry, and, consequently, enhanced the price. Though the gentleman, the yeoman, and the capital rack-renter may sometimes rear enough for the supply of their own table, yet it is not an object with them to produce a supply for the public, and the business of breeding poultry for the market is either left to the cottager, whose means and opportunities are too limited, or to the little tradesmen and farmers. When markets are too distant for the cottagers, their poultry is purchased by the higglers, who carry it to the large towns for sale.

1980. *Hatching chickens by artificial heat* may be mentioned as one of the modes of increasing food, perhaps deserving of attention. This method, we are informed by Diodorus and Aristotle, was practised from time immemorial by the Egyptians, and is still used in that country to a considerable extent. This art is practised very successfully by the inhabitants of a village named Bermé, and by those who live at a small distance from it. Towards the beginning of autumn, the persons who follow it as a trade spread themselves into various parts of the country, and each one offers his services in managing an oven. The ovens are of different sizes, but generally hold from 40,000 to 80,000 eggs. Each Bermean engages to deliver two thirds as many chickens as he receives eggs; and as many of the remaining third as he hatches are his own property. From a newspaper, published by the Egyptian government, it appears that upward of seventeen millions of chickens are annually hatched in this manner in Egypt; and the fowls, when grown up, are not inferior to those produced by incubation.

The members of the French Academy, in the early and middle part of the last century, in consequence of the reports of travellers, made experiments on this subject, under the direction of Reaumur; the trials succeeded, and the details of the methods employed were published in a volume, which was translated into English in 1750. These experiments were repeated by various individuals, not only in France, but at Florence, and in Poland. M. Bonnemain, a physician of Paris, succeeded, in 1777, in hatching chickens in an apparatus heated by hot water; and it is said that chickens produced in this way supplied the table of Louis XIV.

1981. *We give the method used by M. Bonnemain*, which is interesting, because it appears to have been the first example of the mode of producing a very uniform degree of temperature, by means of hot water, now extensively employed in warming buildings.

A box in a wooden building was constructed for hatching the eggs, provided with many shelves in the inside, in which the eggs were placed;* pipes proceeding from a boiler passed between all the shelves, and the heat was kept up by the circulation of hot water through them. The fire being lighted, the temperature is raised till the heat is obtained in the box which is necessary for incubation, which is about that of the human body, or 98°; and this is ascertained by a thermometer placed in the box. It is convenient not to cover, on the first day, more than the twentieth part of the superfices of the shelves, and to add every day, for twenty days, an equal quantity of eggs, so that on the twenty-first day the quantity of eggs first placed will be for the greater part hatched; and we may thus obtain every day nearly the same number of chickens; but this, nevertheless, may be occasionally regulated by the particular season of the year. During the first days of incubation, whether natural or artificial, the small portion of water contained within the substance of the egg evaporates through the pores in its shell; this is replaced by an equal portion of air, which is necessary to support the respiration of the chick; but as the atmospheric air which surrounds the eggs in the box at that degree of temperature is completely dry, or but little humid, so the chick would greatly suffer, or finally perish from this kind of desiccation, were not some remedy provided; and thus, in order that the eggs may be better hatched in the dry seasons, the hens cover them with the earth on the floor of the place where they sit. In artificial incubation, to keep the air in the stove constantly humid, they place it in flat vessels, such as plates, filled with water. When the chickens are hatched, they are removed from the stove, and carried to another box called the cage, where they are fed with millet, and nestle under a sheep's skin with wool in it suspended over them; this is called an artificial mother, and is to supply the place of the shelter afforded by the hen. They also separate, by means of partitions in the cage, the chickens as they are hatched each day, in order to modify their nourishment agreeably to their age. The heat in the water, and, consequently, in the box, is very accurately regulated by means of an apparatus very ingenious, but too complicated to describe in this place. The complete details may be seen in Gill's "Technological Repository," Feb., 1828, p. 70.

1982. *Lately, the public has been amused by the exhibition, in London, of a mode very similar of performing the same process*, which appears to be completely successful. A large box is divided by shelves in the manner of the hot closets that are heated by steam; each division, into which the eggs are laid in flannel, is surrounded on the top, bottom, and sides by steam, and kept exactly to the same temperature. By doors opening into the several divisions, the eggs are perfectly accessible, but must be turned every twenty-four hours. On the eighteenth day the audible sign of life is apparent, by the faint piping of the chick being heard; and on the twentieth or twenty-first day the young creature liberates itself from its prison by breaking the shell in a curious manner with its bill, and by the muscular exertions of its limbs emerges into a new existence. It is curious to see the little animals run about and peck their food, which is ground biscuit, and hard eggs chopped, almost immediately after their birth. These are then put into a low glass case, the floor of which is covered

* A wood-cut of Bonnemain's apparatus is inserted in the section "On Warming Buildings by Hot Water"

with gravel; and in a few days they acquire strength enough to be removed into a larger space on the floor, also covered with gravel. The food is scattered among the gravel, and they feed themselves from the time of eaving the eggs. Upon the whole, the process of hatching in this manner appears to be very simple; but whether it would be profitable, as a speculation, to breed up chickens thus for the market in this climate, where the difficulties will be found much greater than in Egypt, remains to be ascertained by an experiment, which, however, deserves to be made. In New-York, where the climate is severe, they contrive, by means of artificial heat, to make the hens lay all the winter, and likewise breed up chickens.

1983. *Artificial incubation is practised among the Chinese.* Whole swarms of ducks are bred in barges surrounded with projecting stages, covered with coops for the reception of these birds, which are taught by the sound of the whistle to jump into the rivers and canals in search of food, and by another call to return to their lodgings. They are usually hatched by placing their eggs, as the ancient Egyptians were wont to do, in small ovens or sand-baths, in order that the same female may continue to lay eggs throughout the year; which would not be the case if she had a young brood to attend. The ducks, when killed, are usually split open, salted, and dried in the sun, in which state they afford an excellent relish to rice or other vegetables.

1984. *In the following description of birds employed as food*, we have not considered it as essential to arrange them according to the classification usually adopted in treating of their natural history, but rather according to their relative importance as food. They are, however, also grouped according to their natural classes, as nearly as is consistent with our view.

Sect. II.—common or domestic fowl (*Gallus Domesticus*, Linn.).

1985. The tame or domestic fowl, so common with us, is supposed to be derived from some of the wild species which are found in great plenty in the forests of India; but they have been domesticated from time immemorial.

1986. Like other domesticated animals, they have been divided into different breeds, of which those most esteemed here are, the common dunghill or barn-door fowl, often white, but also of every variety of colour; the Dorking; the black or Poland; the Bantam; the game fowl; and the Chittagong or Malay. Besides these, there are several others more rare.

1987. *The common dunghill fowl*, known also by the name of the barn-door, white, or English breed, is of a middle size, and will become fat upon the usual run of the farm-yard, where they thrive upon the offals of the stable and other refuse, with perhaps some small regular daily feeds. At threshing-time they become particularly fat, and both from the full allowance of corn and the constant health in which they are kept, by living in a natural state, and having the full enjoyment of air and exercise, they become the most delicate and high-flavoured of all the varieties.

1988. *Dorking fowls* take their name from Dorking in Surrey, celebrated for breeding them in great plenty and perfection. They are a large and handsome variety, and the flesh is fine, but inclined to a yellowish shade. The lay large eggs, and the capons are generally made from this breed, which has frequently five toes.

1989. *The Poland breed* is black with white tops. Their form is plump; they fatten well, and in quality they are similar to the Dorking, or, rather, superior. They lay abundance of large eggs.

1990. *The every-day, or Dutch fowls*, are smaller than the above, but have still longer plumes, so large, indeed, that their feathers should be cropped occasionally, or they will get into their eyes and blind them. They are called "everlasting layers" from the abundance of their eggs.

1991. *The bantam* is an extremely small variety, originally from India, remarkable on account of its grotesque figure, being generally feathered to the toes. From its size and delicacy, they are very convenient, as they may sometimes stand in the place of chickens, when these are not to be had; and they are particularly useful for sitting upon the eggs of partridges and pheasants, being good nurses as well as layers.

1992. *The game fowls* are rather small; but the flesh is beautifully white, and superior to that of any other variety in richness and flavour. The eggs are small and very delicate; but the chickens are difficult to rear, from their pugnacity of disposition, for which this breed is so remarkable. Great cruelty has been exercised with this animal in making them fight; but it is to be hoped that such unmanly sports will disappear.

1993. *The Chittagong* is an Indian breed, and the largest variety of the species; colour, striped. Their flesh is coarse, dark, and best calculated for soup. They are good layers, but not steady sitters.

1994. *The term chicken* is applied to the young female till they are four months old; after which they are *pullets* till they begin to lay, when they are *hens*. The male is a *chicken* till he is three months old: he is then a *cock-bird* till twelve months old, when he is a *cock*. When deprived of the faculty of procreation, he becomes a *capon;* and a female in the same condition is a *hen-capon*.

1995. *Though in general fowls, when in health, will become sufficiently fat by having plenty of food, with air and exercise*, yet they are commonly fattened for the London market. The means usually employed are, to keep them in confinement, with abundance of food, and little light; so that, in fact, they have nothing to do but to eat. It is a common practice with some housewives to coop their barn-door fowls for a week or two, under the notion of improving them for the table, and increasing their fat: a practice which, however, seldom succeeds, since the fowls generally pine for their loss of liberty; and, slighting their food, lose instead of gaining additional flesh. Such a period is, in fact, too short for them to become accustomed to confinement.

1996. *Fowls are generally fattened by being confined in coops for several weeks.* The privation of light, by inclining fowls to a constant state of repose, except when moved by the appetite for food, promotes and accelerates obesity; but such a state, observes Mr. Mowbray, obtained in this way, cannot be a state of health, nor can the flesh of animals so fed equal, in flavour, nutriment, and salubrity, that of the same species fed in a more natural way. Economy and market interest may, perhaps, be best answered by the place of darkness and close confinement; but a feeder for his own table, of delicate taste, and ambitious of furnishing his board with the choicest and most salubrious viands, will declare for the natural mode of feeding; and in that view, a feeding-yard, gravelled and turfed, a room being open all day for the fowls to retire in at pleasure, will have a decided preference, as the nearest approach to the barn-door system.

1997. *Some places are remarkable for the feeding of poultry:* North Chapel and Kinsford, in Sussex, are mentioned by Rev. Arthur Young. Barley and wheat meal are the bases or chief ingredients in all fattening mixtures for chickens and fowls; but in Sussex the food given them is ground oats made into gruel, mixed with hog's grease, sugar, pot-liquor, and milk; or ground oats, treacle and suet, sheeps' plucks, &c. With these mixtures they are *crammed*, and kept in a coop for a fortnight, when they become fat, and are sold to the higglers. Some of these fowls, when full grown, have been known to weigh seven pounds and more. Oakingham in Berks is another place famous for fattening fowls. The method employed is nearly the same as has been just mentioned. If kept too long upon this food, fever is induced by a constant state of repletion, which renders the flesh red, and frequently kills them. It appears utterly contrary to reason, that fowls fed upon such greasy and impure mixtures can produce flesh and fat so firm, delicate, and wholesome as those which are fattened upon more simple and substantial food. In the system of cramming there are sometimes cruel practices, with the mention of which we do not wish to stain our pages. It is remarked by the best judges that, where artificial feeding is required, the best method is to have feeding-houses constructed, warm and airy, with dry floors covered with sand and gravel, and kept very clean; food should be given in abundance, but of a natural and simple kind, made of grain, oatmeal, milk, boiled potatoes, bread, and sometimes mixed with a little dripping, not more than twice a day, so as to preserve perfect health. The counties of England most productive of poultry are Norfolk, Surrey, Sussex, Herts, Devon, and Somerset. Spring is the best season for breeding chickens; but the attempt to rear winter chickens in this climate seldom succeeds. The spring pullets, properly fed, are particularly fine.

1998. *In the opinion of physicians, both ancient and modern, the flesh of the chicken*, at three months old, is the most delicate and easy to digest of all other animal food; thence it is the best adapted for the stomach of invalids, or the constitutionally weak. Age makes a striking difference in the flesh of fowls; after twelve months it becomes tougher and more insoluble; the male, indeed, at that age, is only fit for making soup, while the pullet is still excellent, although a more substantial viand than the chicken. While young the cock and hen are equally delicate. The capon, when not made excessively fat, has been esteemed one of the greatest delicacies, preserving the flavour and delicacy of the chicken with the juicy maturity of age.

The mode of killing, by drawing or stretching the neck, when unskilfully performed, it may be proper to mention, is productive of great and unnecessary suffering to the animal: sufficient force should be used to break the spinal cord, otherwise death does not ensue immediately.

The common fowl belongs to the order Gallinæ, or gallinaceous birds, which also comprehends the turkey, pheasant, partridge, bustard, peacock, and quail.

Section III.—Guinea Fowl (*Meleagris Numidia*, Linn.).

1999. This bird is so named because first brought from Africa, where only it is wild in great abundance. In a state of nature these birds are gregarious, and are seen in flocks of two or three hundred: they delight in marshy places, but always perch at night upon high trees, or in dry situations. They are about the size of the common hen, but stand higher on the legs. Though domesticated, they retain much of their wild nature, and are apt to wander. They lay very abundantly, and their eggs are excellent. They are not so white in the flesh as the common fowl, but more inclined to the colour of the pheasant; and, like it, the taste is savoury, and it is easy of digestion; by many they are considered as a good sustitute for the pheasant. They are excellent for the table, having somewhat of the same flavour, and they are in season when game is going out.

Section IV.—Turkey (*Meleagris Gallipavo*, Linn.).

2000. This excellent bird is a native of America only. It was introduced into Europe from Mexico, and imported into England from Spain about 1524, in the reign of Henry VIII., since which time they have been successfully bred here, but were so rare in France, that the first which was eaten in that kingdom appeared at the nuptial feast of Charles IX., in 1570.

2001. *The wild turkey* abounds at present in some parts of America, but has become more scarce since the country has been cleared of wood. In March they get so fat that they cannot fly more than three or four hundred yards, and are soon run down by a horseman. In the unfrequented parts bordering on the Mississippi, they may be shot with a pistol. In this state they are black, or a beautiful bronze and green; but domestication produces considerable variety in their colour. The usual weight of the wild turkey is about thirty pounds: it frequents swamps, but repairs to the woods to roost, and feeds upon berries, acorns, and other wild fruit, as well as herbs. Their flesh is excellent.

2002. *There are three varieties in this country:* the black, the copper or speckled, and the white. The black is the nearest to the natural stock, and is larger and more hardy. These abound in Norfolk, and are esteemed superior to others; they often weigh fifteen pounds, particularly when crossed by the large Virginian. It is said that their superiority is chiefly owing to the dryness of the soil in that district; they are brought up by every little farmer in the county, which furnishes the largest supply to the London market; but they do much mischief to the field crops, which prevents many farmers in other parts from keeping them. The white variety is rare here, though common in France.

2003. *The flesh of the turkey* is white, tender, delicate, nutritive, and restorative, of excellent flavour, and more dense and substantial than that of the chicken. Age produces a similar effect as in the chicken: when old, it is good for little except stewing.

The usual mode of killing this bird is tedious: it is bled to death by dividing the blood-vessels under the tongue, the object of which is said to be to make the flesh whiter by extracting the blood. The method may appear cruel, but it does not appear that bleeding to death is attended with much pain to any animal.

Sect. V.—pheasant (*Phasianus colchicus*, Linn.).

2004. This beautiful bird, adorned with rich and splendid plumage, is of the same genus with the common fowl, and crows not unlike the cock. It is said to have been discovered by the Argonauts on the banks of the Phasis, near Mount Ararat, in their expedition to Cholchis, whence the name; and so highly was it thought of by the Greeks, that when Crœsus, king of Lydia, seated on his throne in all the pomp of eastern splendour, asked Solon, then his guest, whether he had ever seen such magnificence before, the philosopher replied that he had seen the beautiful plumage of the pheasant, which he thought superior. The common European or English pheasant has been long naturalized in the warmest and most woody counties of England, and is brown, with less brilliancy of colouring than some foreign varieties which have lately been introduced as fancy breeds, such as the gold and silver pheasants, natives of China, the ring-necks, natives of Tartary, the Bohemian, &c. The golden pheasant is the largest and most hardy.

2005. *The common pheasants are much prized in parks for their beautiful plumage, and are carefully protected as game on account of the delicacy and fine flavour of their flesh.* They feed upon all sorts of insects, like the peacock, as also upon small fruits and seeds, and require woods to shelter them. The cock is voracious and cruel.

2006. *They may be domesticated, though not easily;* but the flesh of those brought up in the house is not comparable to that of the wild pheasant. Upon this bird M. Ude observes: "It is not often that pheasants are met with possessing that exquisite taste which is acquired only by long keeping, as the damp of this climate prevents their being kept so long as they are in other countries. The hens, in general, are the most delicate. The cocks show their age by their spurs. They are only fit to be eaten when the blood begins to run from the bill, which is commonly six days or a week after they have been killed. The flesh of the pheasant is white, tender, and has a good flavour, if you keep it long enough; if not, it has no more than a common fowl or hen." It is in season from October to February, is best a year old, and fat. This bird is very common in France, and, before the Revolution, used to be a great nuisance to the farmers, even near to Paris.

Sect. VI.—partridge (*Tetrao Perdrix*).

2007. *Partridges are to be found in all the temperate countries in Europe,* but are unable to sustain rigorous cold or intense heat: they are most abundant in the Ukraine. They were formerly so common in France that the cultivators were obliged to sow three or four times the corn that was necessary to raise a crop, so destructive are they to the grain. They delight in the concealment of corn-fields, feeding, like the pheasant, upon insects and seeds, and are particularly fond of wild mustard. When the winter comes on, they retire to the upland meadows, and hide themselves among the grass. The partridge is a timorous and simple bird, and is easily taken: it has not been domesticated, though it might be reared like the pheasant.

2008. *It is not equal in point of flavour to grouse, but is considered as a table luxury* in England. Partridges should be chosen young; old birds are good for nothing: when young, they are generally distinguished by a dark-coloured bill and yellow legs; as they get older, the legs turn gray. There is a red-legged partridge, but it is rare in England. The season for the common partridge is from September to February. Partridges, when young, covey together, and thus the sportsman often shoots several at once.

SECT. VII.—BUSTARD (*Otis Tarda*, Linn.).

2009. *This is the largest land bird of Europe*, the male weighing from twenty-five to thirty pounds, and is a native of England. There were formerly flocks of bustards in forty or fifty, in this country, upon the wastes and in the woods, particularly in Norfolk, Cambridgeshire, and Dorset, as well as in various parts of Scotland; but they are now very rarely seen wild here, though still common on the coasts of the Mediterranean. The bustard runs with great rapidity, so as to elude the pursuit of common dogs, but falls a victim to the greyhound, which often overtakes it before it can commence its flight, the preparation for which, in this bird, is slow and laborious, and it flies with great difficulty. The hunting of the bustard was an ancient diversion. The head and neck of the male are ash-coloured; the back barred transversely with black; the belly is white. Their flesh has been ever held most delicious, and they feed principally upon grapes, grain, and worms. The male is distinguished by a circumstance wanting in the female, which is the possession of a large pouch from the throat to the breast, capable of holding several pints of water. They are bred occasionally, feeding like the turkey; and it would appear that they are an object peculiarly deserving of attention with regard to propagation and increase, as it is probable that its flesh will well repay the expense of its food. Bustards are sometimes to be had in Paris, but they are expensive fare, costing generally 4*l.* or 5*l.* each. Captain Cook discovered a prodigious number of them in a bay of Australia, which is, in consequence, named Bustard Bay. Besides this large species, a smaller species sometimes appears in England (*O. tretrax*) not larger than a pheasant.

SECT. VIII.—QUAIL (*Tetrao Coturnix*, Linn.).

2010. *This bird is a native of the East*, and abounds in the Greek islands of the Archipelago, and in Italy. It also inhabits Egypt, and formed one of the supplies which the Israelites obtained while in the wilderness. Quails are birds of passage, and migrate from warmer regions in the spring to colder in autumn. It may be said, indeed, to be a universal inhabitant of the old Continent, but not of the new.

2011. *Quails are found, though rarely, in England;* some entirely quitting it, others shifting their quarters from one country to another, and sheltering themselves, on the approach of winter, among the woods near the sea-coast. They are not domesticated here, and may be reared and preserved in the same manner as the pheasant and partridge; their food is nearly the same as that of the latter bird: when wild, they frequent corn-fields and meadows, and are ensnared by sounding a quail-pipe, an instrument made to imitate the voice of the hen. They are very abundant in France, and are caught in snares, and sent both to Paris and to the London market. The island of Capri, near Naples, produces such vast numbers of them, in consequence of its bishop's income having been formerly paid from the profits arising from them, that the island is sometimes called the Bishopric of Quails. So many as 800,000 have been taken near to Naples in one day; and Buffon states that sometimes clouds of them are seen on the French coast. They are sometimes imported from Turkey and the Greek islands, preserved in fat or clarified butter. With us, they are occasionally seen alive, fattening in cages; and at the poulterers' they sell for three shillings each. Some persons esteem them; but M. Ude says, "Quails, in my opinion, have no flavour; it is only their rarity that makes them fashionable." They are good only when fat. This bird was proverbial among the ancient Greeks as captious and quarrelsome; and quail fighting was one of the sports of the Athenians, as it is among the Chinese in the present day.

SECT. IX.—PEACOCK (*Pavo Cristatus*, Linn.).

2012. *This beautiful and majestic bird is a native of India*, and is found in a wild state in Java and Ceylon, where they perch upon trees like the turkey in America. When the conquering Alexander led his armies into the peaceful plains of India, he is said to have been so struck by the sight of the peacock in the full magnificence of its plumage that he forbade any one to destroy them under pain of death: but its antiquity we learn from the history of King Solomon, and the choice of the goddess Juno, who regarded it as her favourite bird. The peacock has been introduced on the table by the ancients as well as by the moderns, but rather as a showy and ornamental dish, being preserved in some of its fine plumage.

2013. *The flesh is coarse and ill-coloured*, and is scarcely ever eaten in these times. At three years old the splendid tail is complete; and it lives to the age of twenty years. Its chief value is as an ornament to pleasure-grounds, where it is useful in destroying reptiles.

SECT. X.—SWAN (*Cygnus Mansuetus*, Linn.).

2014. *It is now known that the wild swan (Cygnus ferus) is a distinct species from the* *tame bird of the same name.* The trachea or windpipe in the latter is simple and straight; but in the wild swan, after entering the chest a little way, it is reflected from thence in the form of a trumpet, and, again returning, divides into two branches. This structure enables the bird to make the powerful note which it utters in its flight, and which can be often heard when the bird itself is so high as to be invisible.

2015. *The wild swan is gregarious and migratory.* It visits Britain occasionally, and may be seen resting in flocks of five or six, but does not remain here long. It is rather smaller and more slender in its form than the tame species. The flesh of the wild swan is not only eatable, but is held in much consideration in the North of Europe and in America.

2016. *The tame swan* is chiefly esteemed with us as a favourite ornament in sheets of water in parks; for its flesh is ill-flavoured except when they are young, or cygnets, when it resembles the pigeon in taste. It is remarkable, however, that the Romans considered the swan as a great delicacy, while the flesh of the goose was reckoned by them impure and indigestible.

2017. *In former times the swan was served up at every great feast in England* as a dish of state, when the elegance of the table was measured by the size and quantity of the cheer: cygnets were fattened at Norwich for Christmas fare.

Sect. XI.—goose (*Anser Domesticus*).

2018. *The goose is pretty generally spread over the globe,* being met with in Arabia, Persia, North America, Lapland, and Iceland. The colour of the wild goose is uniformly gray, and the taste of the flesh strong and fishy. It frequents the fens of Lincolnshire and other places, and breeds there in the summer; they appear there in large flocks, and are migratory. They are easily tamed and domesticated, which produces a change in the colour of their plumage, no two being then exactly alike, though the predominating colour is white.

2019. *The varieties of the goose are very great* in different parts of the world; but we have only one species in England in common use, which appears to be an English breed. The Chinese and the Canadian goose are kept sometimes, but only for ornament, in pleasure grounds.

2020. *The best geese in England* are probably to be found on the borders of Suffolk and Norfolk, and in Berkshire; but the largest flocks are kept in the fens of Lincolnshire and Cambridge, many persons there having 1000 breeders. Geese, being aquatic birds, thrive best when they have access to water, as in fens, marshes, and grassy-margined pools. Vast droves are sent from the fens every year, to be fattened by the London poulterers. Besides these, prodigious numbers are kept all over the kingdom, on commons, in farmyards, and by cottagers. Part of these provide themselves with food in the summer and harvest, when they are turned in among the stubble to fatten upon the scattered grain.

2021. *The natural food of wild geese* is chiefly of an animal nature; but the tame goose feeds upon vegetables, as grass, corn of all kinds, with garden vegetables, raw or boiled. They are easily fattened by allowing them plenty of food and liberty. In some places it is the custom to cram them; and cruel methods are employed in France and Germany to produce large and fat livers, from which are prepared the celebrated *pâtés*. We are informed by Mrs. Trollope, that "There is one much-prized delicacy that never fails at Vienna; the *pâté de foie gras* seems to be considered as indispensable. Out of twenty-one dinner tables, I have missed it but at two; and as, moreover, no ball-supper is considered as perfect without it, the number of invalided geese must be greater than it is agreeable to think of." Some prefer a goose entirely fattened on the stubble, granting it to have been previously in good case; an over-fattened goose is too oily for delicate flavour. When required to be fattened, feeding-houses are best, where they may be given oats, pease, and bean meal, pollard mixed with the skimmed milk with plenty of water, and clean beds of straw.

2022. *The goose, though apparently a stupid bird, is roused by the least noise in the night,* and the immediate cackling converse which they begin to hold in the approach of apprehended danger is considered as a valuable safeguard, a memorable example of which was their saving the Capitol of Rome from an attack by the Gauls.

2023. *Though greatly relished by some persons as food,* it is not a universal favourite. The flesh abounds in flavour, and is considered to be highly stimulant. When young it is tender, but, in general, it is only adapted for good stomachs and powerful digestion, and should be sparingly used by the sedentary and weak, and by persons subject to cutaneous diseases. Its strong flavour is by some thought to require modification by stuffing with sage and onions, though others relish it only when this is not demanded. From the various parts, however, many savoury dishes are prepared, for which we refer to the receipts on that subject. The fat is reckoned peculiarly subtle, penetrating, and resolvent, and is usually preserved for domestic applications.

2024. *The average weight* of the large kind of geese is from nine to fifteen pounds, and instances have been known of their weighing thirty pounds when fully fattened; but the smaller breeds are preferable for the table.

2025. *It is generally considered that geese are in the greatest perfection about Michaelmas,* because then they have had the feeding upon the stubble after harvest; but, says Dr. Kitchener, though "a Michaelmas goose is as famous in the mouths of the million as the minced pie at Christmas, yet for those who eat with delicacy it is at that time too full-grown. The true period when the goose is in the highest perfection is when it has just acquired its full growth, and not begun to harden. If the March goose is insipid, the Michaelmas goose is rank; the fine time is between both—from the second week in June to the first in September."—*Cook's Oracle.*

In England the goose is sacred to St. Michael: in France to St. Martin. The Michaelmas goose is said to owe its origin to Queen Elizabeth's dining on one at the table of an English baronet on that day when she received tidings of the dispersion of the Spanish Armada, in commemoration of which she ordered the goose to make its appearance every Michaelmas.

2026. *Geese are called green* till they are four months old. They are roasted with pepper and salt only, instead of being stuffed with sage and onion like full-grown geese. These are, of course, early in the season, when the price is high.

2027. *Geese are in some places dried and smoked:* the smoked geese of the Orkneys used to be famous; at present they are little used.

2028. *It is not altogether on account of their use as food that this bird is valuable;* their feathers, their down, and their quills have long been considered as articles of more importance, and from which their owners reap more advantages. In this respect, the poor creatures have not been spared: urged by avarice, their inhuman masters, in some places, appear to have ascertained the exact quantity of plumage of which they can bear to be robbed, without being deprived of life. Mr. Pennant, in describing the methods used in Lincolnshire, in breeding, rearing, and plucking geese, says they are plucked five times in the year; first, at Lady Day for the feathers and quills; and this business is renewed, for the feathers only, four times more between that and Michaelmas: he adds, that he saw the operation performed upon goslings of six weeks old, from which the feathers of the tails were plucked; and that numbers of them die when the season afterward proves cold. We will not vouch that this is the present practice.

2029. *The Canada goose* is so numerous in Hudson's Bay as to form a principal part of the food of the English there, who, in favourable years, salt and barrel vast quantities of them. They are chiefly taken by the Indians, who have the talent to imitate their cackling, and thus decoy them within reach of their shot. Captain Ross describes them as of exquisite flavour. Their feathers are sent to England.

2030. *The so-called Solan goose* is frequently eaten in the Hebrides of Scotland; but their flavour partakes of that of their fishy food; this, however, they loose when they are salted and smoked for winter's store; in that state they are much relished by the inhabitants. We may just observe that this bird is not arranged by naturalists in the genus *anas;* it is, in fact, not a goose, but a pelican (*Pelicanus Bassanus*).

Sect. XII.—duck (*Anas Buschus*, Linn.).

2031. *The duck is a native of Britain,* and frequents the edges and banks of lakes in most parts of Europe. The tribe called *anas* of Linnæus is very extensive, and comprehends several families of aquatic birds, as the swan, goose, duck, teal, and widgeon, distinguished by being web-footed, and having a flat bill with the edges divided into teeth.

2032. *The wild duck* makes its summer abode in the desolate, fenny parts of our island; and when the severity of winter deprives them of food, necessity forces them to retire towards the sea in numerous flights, where they find water unfrozen, and where they remain till the return of summer. The flesh of the wild duck is not so general a favourite as that of the tame bird; when they are taken on the seacoast they have usually more or less of a fishy flavour; but those from the fens of Lincolnshire are free from that rankness, and have a fine, rich, gamy taste: these are much esteemed as being very savoury, and are sold by the poulterers in London, at a reasonable price, in the season. There are many varieties of the wild duck in foreign countries.

2033. *Great numbers of wild ducks are taken by a singular contrivance called decoys,* which are places into which they are allured by ducks bred up for the purpose. These decoys consist of a pond surrounded by wood in a marshy country. From the pond several canals lead in different directions, and terminate in a narrow ditch that is closed at last with a funnel net. Over these canals are arched hoops, and upon them a continued netting. The wild ducks settle on the pond to feed, and the decoy man is concealed behind a screen of reeds. The decoy ducks are trained so as to lead the way in search of food into the canals, and the wild birds follow; the decoy man then appears, and drives them farther up, where ultimately they are taken in the nets in great numbers. There are many of these decoys in the fens of Lincolnshire, from which the London market is supplied.

Among other methods of catching wild ducks, the ingenious mode so characteristic of the Chinese may be mentioned. Large hollow gourds are purposely thrown into the water in great numbers, and allowed to float about. The birds being at length accustomed to approach them with impunity, their captors disguise themselves by placing similar gourds over their heads, with holes to see and breathe through, very much in the manner of a helmet. Then, wading quietly along the shallow waters, they have only to approach the birds gently, and pull them under water by their legs in succession. The same method is practised by the American Indians.

2034. *Tame ducks* are well known to be greedy, and not nice feeders. They require a mixture of animal with vegetable food, being accustomed, in the natural state, to live on worms, which they are always seeking for in the water. They will eat flesh and garbage of any kind; but water insects, vegetables, corn, and pulse, are their proper nutriment. If fed much upon grain they fatten rapidly, and the flesh becomes delicate, but is apt to be insipid; and if fed too much upon animal food, their taste is strong, and more like wild fowl. They require water, and that which is stagnant is best, as affording more nourishment from weeds and insects. They are sometimes fattened in coops; but they become of a more delicate flavour, fatten equally well, and are more wholesome by having access to a pond with plenty of food. Their flesh is savoury and stimulant, and is considered to be less gross than that of the goose, as well as more easily digested.

2035. *The character of the duck* is particularly inoffensive and harmless, and is even distinguished by its social disposition. It is also valuable for its great fecundity, and the cheapness and ease with which it may be provided for.

2036. *Though ducks are well known on the table in the time of green pease*, yet Ude says that "November is their proper season, when they are plump and fat." By artificial means they may be had in their prime about Christmas, and this object is effected in some parts of England by preventing the laying of the eggs until the end of autumn; they are then hatched, and the birds fattened.

2037. *Ducks' eggs* are, in general, easily distinguished from those of the fowl, being more of a bluish colour, though some are nearly as white. When boiled, the white is never so curdy as that of the hen, but a little translucent, even when set, and the yolk is darker in colour. They have a peculiar flavour, which some dislike and others prefer; but they have a more binding quality, and are therefore preferable to hens' eggs for making puddings and pastry: a property which, in France, occasions them to be much sought after for omelets and cakes.

Sect. XIII.—widgeon.

2038. The widgeon is a smaller bird of the duck genus, but not so good as the wild duck. It is often fishy and rank, and the flesh is dark and dry; some, however, consider it as well flavoured, and a good wild fowl. It is in season from October to December.

Sect. XIV.—teal.

2039. This is the smallest of the duck tribe, and much superior to the widgeon. It is, indeed, favourite game.

Sect. XV.—pigeon (*Columbus*, Linn.).

2040. This genus is found in all the warm and temperate regions of the globe, particularly in the former; and so numerous are the species, that above a hundred have been enumerated; most of these are wild, but several have been domesticated.

2041. *We have in England two species of wild pigeons* distinct from the domesticated species. The *wood pigeons* or *ring-doves* (*Columba Palumbus*, Linn.) build their nests on lofty trees, as the beech, elm, and oak, and are thought to migrate from the northern to the southern parts of the island, according to the season of the year: they appear sometimes in considerable flocks, and afford much amusement to the sportsman, while their flesh is highly prized. They are of a bluish ash-colour, the neck green and copper-colour, with patches of white. In Carolina they appear in such numbers that they darken the air in their flight, and are found to be so fat that oil is extracted from them. The *turtle dove* is another wild species, of an elegant form but diminutive size, that visits us in spring and disappears in September. It builds its nest in deep recesses of the woods, but is not plentiful.

2042. *The stock dove is the original of our domesticated pigeons*, and is sometimes in a wild state. In its natural state it is of a deep-blue and ash-colour, the breast of a changeable green and purple; on its wings are two bars of black; on the quill feathers another, and also black on the end of the tail; the back white. It inhabits the hollows of rocks and other similar situations. In its domestic or cultivated state the pigeon runs into a number of beautiful varieties, the culture of which forms a particular kind of business: thus we have the carriers, croppers, pouters, horsemen, runts, and a number of others, known to the fancy breeders.

2043. *The blue dove house pigeon* is rather larger than the wild, and is the only variety that is bred up for the table in this country in great numbers in farmyards. Tame pigeons live entirely on grain, pease, small beans, and seeds; they are very ravenous, particularly when young, consuming a great deal of food, and, consequently, are costly When young, and still fed by their parents, they are called *squabs*, and are then prefer able for the table; under six months old they are termed *squeakers;* and at six months they begin to breed: the old bird is tough, dry, and insipid. The flesh of pigeons is highly savoury, delicate, and stimulating, and is dressed in a great variety of ways, of which the most common with us is making it into pies. The dark-coloured pigeons are considered to have the highest flavour, but the light-coloured to have the most delicate flesh. They breed fast, and, when well supplied with food, will furnish squabs every month in the year. But they are kept less than formerly, being found extremely destructive to the crops, particularly of pease, the loss of which to the farmer is very considerable.

Sect. XVI.—lark (*Alauda Arvensis*, Linn.).

2044. The lively notes of this little songster cannot save it from the gormandizing powers of man.

2045. *Though so small, larks have, it seems, always been sought after as an exquisite morsel.* They were not only caught, but reared and fattened for the Roman epicures; and our markets are abundantly supplied with them, being captured in the winter season, from September till February, in immense numbers, particularly about Dunstable, Cambridge, &c. It is remarkable that the propensity which they have to fly towards a light is converted into a method of decoying them. Mirrors reflecting the sun's rays are placed so as to revolve and attract them into nets placed to ensnare them. They are generally roasted, many together, on a lark spit, and are among our greatest delicacies. It is reckoned that 4000 dozen are annually sold in London.

Sect. XVII.—crane.

2046. *The crane belongs to a class of birds called Grallæ*, or waders, distinguished by the length of their naked legs, walking, as it were, upon stilts, the signification of the Latin word grallæ. The birds in this class are the crane, heron, stork, bittern, plover, snipe, coot, rail, and a few others. All of them seek their food, consisting of small fish, worms, and insects, in shallow water and marshes, but they likewise eat grain. The crane is migratory, and now a rare visitant to us, though it was once a constant inhabitant of Britain, and was formerly so great a favourite that there was a penalty for destroying its eggs. Its flesh is coarse, except when young.

2047. *The heron and stork* are never eaten with us at present, although, like the crane, they were once common at feasts: in France the heron was formerly considered as royal game, and the young highly prized.

2048. *The bittern* is a good deal like the heron, but shorter and rounder in its body. It is considered as an excellent bird, though less esteemed than it used to be.

Sect. XVIII.—snipe.

2049. This is a migratory bird, and one of those whicn are the most generally distributed over Europe. It prefers a cold climate to breed in, but is met with even in India. It is one of the waders, and frequents morasses and places where there is much water, and where worms are abundant; it feeds upon these, but likewise occasionally upon corn and rice. Sir H. Davy informs us that they are extremely fat and delicious during their migration from the north to the south in the marshes of Italy and Carniola, and then resemble the ortolan of Italy. With us they are fattest in frosty weather, when they haunt only warm springs, where they find plenty of worms or larvæ. A few breed in the marshes of England, but more in the Hebrides and Orkneys.

Sect. XIX.—plover.

2050. The plover is a wild water fowl, but often seeks its food on the arable land in the vicinity of the sea. It has a peculiar cry, which is easily imitated by the sportsman, and is thus lured to its destruction. They roost on the ground, and are sometimes taken with nets by hundreds. There are two species of this bird, the gray and the green; the former being somewhat less than the woodcock, though larger than the green. The green plover is generally preferred for its flavour, but both are inferior to the woodcock. Prodigious flights of these birds, consisting of many thousands, are to be seen in the Hebrides and other parts of Scotland; and in the winter such numbers are sent to London that the market is sometimes quite glutted with them, and they are sold very cheap. They are kept till they have a game flavour, previous to dressing; but though a great favourite with many, they have a peculiar taste not universally relished. Plovers' eggs are considered to be a great delicacy, and are easily to be had from the poulterers; they are generally brought to table boiled hard, but are occasionally eaten raw.

Sect. XX.—lapwing (*Tringa Vanellus*, Linn.).

2051. This is commonly known in England by the name of the *bastard plover.* It is frequent in our fenny counties, and in wet places in most parts of England. In winter they are seen in large flocks. Their flesh is very good, their food being insects and worms. The eggs are of an olive cast, spotted with black, and are much esteemed for their delicacy. Lapwings are taken with nets during October and November, and are sold by London poulterers at three shillings the dozen.

SECT. XXI.—RED GROUSE (*Tetrao Scoticus*, Linn.).

2052. *The beautiful plumage and exquisite flavour of this bird* render it an object of considerable interest. It appears to be a native of Scotland and the north of England, in the mountainous districts of which it is found by sportsmen in great plenty, feeding on various berries that grow among the heather, and also on the tops of this plant; hence it is often called *moor game*, or *moor fowl*. It does not undergo any change of colour in winter, but acquires a greater mass of clothing, and its legs become covered with a sort of hair-like feathers. The breeding season is early in the spring, and the brood continue in company for some months, sometimes joining others which range the high moorlands, where they are shy, and difficult to be approached. Their colour is a rich chestnut, barred with black.

SECT XXII.—BLACK GROUSE (*Tetrao Tetrix*, Linn.).

2053. This bird, called also the *black cock*, or *moor fowl*, is larger than the red grouse, the male weighing sometimes four pounds, and the female two pounds. It is also less common, and therefore more highly prized. It is met with nowhere in Britain but in the Highlands of Scotland and the mountainous heaths of the north of England. Its plumage is a rich mixture of black and blue relieved by markings of white, and its legs are covered with very minute feathers. The form of its tail is remarkable, branching into two crooked expansions. Its food is similar to that of the last described bird. Vast numbers of these birds are found in Norway of large size, being nearly equal to turkeys; and of late many have been imported into London and sold in the shops; but these are not equal in flavour to the Scotch smaller kind.

SECT. XXIII.—WOODLAND GROUSE (*Tetrao Urogallus*, Linn.).

2054. This is likewise called the "cock of the wood," and is the largest among the birds which we denominate game, it being little less than the turkey. It was originally common in the mountains of Britain, but is now nearly extinct with us, occurring only in the Highlands of Scotland, though still abounding in the north of Europe, Germany, and the Alps, where it lives in pine forests, on the cones of which it is supposed to subsist, and which, at some seasons, gives its flesh a terebinthinated taste. It is in general delicious eating, and is sometimes sent to England preserved in ice. From the great delicacy of its flesh, it is to be lamented that sufficient means have not been taken to domesticate it, which, it is supposed by some sportsmen, would be very practicable. Its plumage is extremely beautiful.

SECT. XXIV.—WHITE GROUSE.

2055. The *white grouse*, or *ptarmigan*, is found in the British isles, though not plentifully; the London market is supplied from Scotland and Norway, those from the latter country being preferred. When young it is excellent, and little different from common grouse. At Hudson's Bay they are in such flocks, that sixty or seventy are often taken in a net at once; and, as they are as tame as chickens, they are driven into the nets without difficulty.' A ptarmigan will weigh a pound and a half.

SECT. XXV.—WOODCOCK (*Scolopax Rusticola*, Linn.).

2056. This bird is somewhat less than the partridge, which it much resembles, and is a bird of passage. It breeds in high northern latitudes, as in the marshy and extensive pine forests of Norway, Sweden, Russia, and Siberia, feeding upon worms and insects, which it searches for with its long bill. When winter sets in, woodcocks emigrate and seek a milder climate, the time of their leaving Sweden agreeing with that of their arrival in Britain, where they frequent our woods, particularly in the west and north. In emigrating, they travel slowly, flying low from wood to wood, choosing the night, and concealing themselves during the day. They are with us during the winter, and leave England about the latter end of February, a few only remaining in this country, where they breed. There are woods in England, particularly one in Sussex, near the borders of Hampshire, in which one or two couple of these birds, it is said, may always be found in summer. They have been observed as far south as Asia Minor, Barbary, and Egypt, and they are common in Japan; these probably migrate from the north of Asia. They are taken in great numbers in nets, springes, and with bird-lime, and are served up at the best tables as delicacies, being much esteemed by gourmands as a highly-flavoured viand, resembling the barn-yard fowl in point of delicacy; but they are good only when fat. It is best to keep them before dressing till they are very tender, without suffering them to proceed too far in the progress of decay: they are remarkable for the tenderness of their skin. We are informed, in a contemporary publication, of some curious deceptions practised by the inferior poulterers of London upon genuine cockneys who are ambitious of having game at their tables. "The gray plover is sometimes trussed like a woodcock, its bill cut off, and the bill of a real woodcock inserted instead: the bills of these latter birds being purchased from the cooks of wealthy families." The detection of this fraud, which, it is hoped, is unusual, is obviously to give the bill a "good tug;" and this suggests the necessity of those who wish to purchase wild fowl being themselves acquainted with the characters of the birds, and not trusting implicitly to the sellers.

The woodcock is not considered game by law, since, being a migratory bird, having no settled habitation, and not being reared or preserved, it cannot be considered as the property of any individual.

Sect. XXVI.—Puffin, Kittiwake, and Auk.

2057. These birds live almost entirely in the sea, building their nests in the sea cliffs, and feeding altogether on fish. Though relished by some persons when young, yet their strong and peculiar flavour, derived from their food, prevents their being generally dressed, except in cases of necessity. Pickling and spicing takes off much of the fishy taste. *The sea-gull* is never eaten, the flesh being coarse and strong.

Sect. XXVII.—Swallow.

2058. *The swallow is never among the trifles seen at our tables;* but the *edible birds' nests,* which occupy the first rank among the dainties prized by Chinese gourmands, are the production of a species of swallow (*Hirundo esculenta*). These nests are formed of a transparent gelatinous substance that dissolves in water; they are employed for sauces, or in soups, or chicken broth for valetudinarians, and are reckoned an excellent restorative. This rare material is sometimes seen even at the tables of the wealthy and luxurious in Britain. The nests are about three or four inches in circumference, and one in depth, and are met with in clefts of the rocks on the shores of Cochin China, Java, Malacca, and various parts of the Indian Archipelago. They are found in great quantities in the islands on the Tavoy coast and in the Mergui Islands in Siam. Malay, Chinese, and Siamese boats come every year for six weeks in January to collect them. Taking them is a work of considerable danger, as it is necessary to climb precipices by the help of ropes and flying ladders made of ratans, and many are found in intricate caves. The Chinese, among whom the extremes of luxury and misery are frequent, pay five or six dollars a pound for them; when first brought in their raw state, they are covered with dirt and feathers, from which they are cleared before they are offered for sale. It is said that Batavia alone exports annually 4,000,000 of these nests to supply the tables of the Chinese mandarins. The substance which the bird collects to compose these edible nests does not appear to be yet clearly ascertained. Dr. Mayen, in his voyage round the world, states that the swallow eats a species of marine fucus (Sparococcus *cartalagineus*, var. cetaceus), which grows in great abundance in the Indian seas; and, after permitting it to soften for some time in its gullet, it disgorges the substance, now converted into a kind of jelly, and uses it as a cement for its nest; and it has been said that the Japanese, who have long ago discovered this fact, prepare the substance in an artist-like manner. The vegetable origin of the substance in question has, however, lately been opposed in the "Journal de Pharmacie," August, 1836, by M. Virey, who maintains, with Rumphius, that the swallow collects from the surface of the sea the gelatinous material of some species of marine mollusca, from which it would appear that the edible nests consist of animal substances.

Sect. XXVIII.—Wheat-ear.

2059. *This is a delicate little bird of passage about the size of a lark,* but difficult to be procured at the poulterers' in London, unless ordered. They visit us, and are in season from July to October; they are obtained chiefly on the South Downs in the neighbourhood of Brighton, Eastbourn, and other parts of Sussex, and may be had at Tunbridge Wells. They are caught in nets and snares like larks, and are occasionally captured in immense numbers. They are usually sold at a high price; the larger are sent to London and potted, when they are by many as much esteemed as the ortolan of the Continent; but, from their fatness, they will not keep long without spoiling, and can be had in perfection only in the districts where they are caught.

Sect. XXIX.—Landrail, or Corncrake.

2060. The landrail is known by its peculiar voice, like the sound of a watchman's rattle; and it trusts more to its swift foot among the corn or long grass than to its wings, which it rarely uses. It is seldom caught; but when in good condition, it is reckoned a first-rate delicacy. When fully grown, they weigh about half a pound.

Sect. XXX.—Ortolan.

2061. This small singing bird is considered one of the greatest luxuries of the table. It is migratory, but is never found wild in Britain, though common in France, Italy, and the warmer parts of Europe; consequently, in this country it is rarely procurable, and in its cost may rank with the turtle among the list of expensive delicacies. They are sometimes bred in cages, and are kept in a dark room, where they can have no employment but eating; in consequence, they get inordinately fat, and would die of this disease if the knife did not interpose when they have arrived at the desired point of obesity. When well fed, they weigh about three ounces each, and are roasted with the intestines in them. They are sometimes imported, potted, from the south of France and Italy.

Sect. XXXI.—Eggs.

2062. *Eggs form an important article of food,* and they have been chemically examined by several analysts, particularly Dr. Prout and Dr. Bostock. The eggs of birds are composed of several distinct substances; as the shell, the white, and the yolk.

2063. *The shell,* or external coating, is formed chiefly of carbonate of lime. It consists in 100 parts, of carbonate of lime, 72; phosphate of lime and magnesia, 2; gelatin, 3; the remainder, perhaps, water. It is supposed that birds pick up carbonate of lime with their food to supply materials for the shells of their eggs; for it is remarked, if care be taken that their food shall contain none of this earth, they will lay eggs without shells.

Egg-shells, on account of their calcareous nature, are often employed for the same purposes as chalk or lime, in correcting acidities, &c. They are observed to be filled with numerous minute pores, which should be closed by rubbing some substance over them when the eggs are to be preserved. The *thin membrane* immediately beneath the shell is, in some eggs, much stronger than in others, and is considered to be coagulated albumen.

2064. *The white of egg* is generally mentioned as being composed only of albumen, and, indeed, is referred to often as an example of pure albumen; but Dr. Bostock has given the most complete analysis of it, from which it is shown to consist of 80 parts water, 15 albumen, and 4·5 mucus. It is a glairy, insipid fluid that mixes readily with water when raw, and is often used as a varnish, like gum; it is also employed to clarify liquors. It much resembles serum of blood in its composition and properties. The white of the egg has been found, by accurate observation, to consist of two parts: the external part, or that immediately under the membrane that lines the shell, is always most abundant in newly-laid eggs. When the egg is raw, this part is almost as liquid as water, and evaporates by keeping. In eggs that have been long kept, it is scarcely observed; the inner white is by much the most considerable, and this sets, or acquires a firmer consistence, in boiling. Newly-laid eggs are heavier than water, and sink in it; but, in consequence of the evaporation of the internal white through the pores of the shell, they become lighter; hence old and bad eggs swim in water. Hens' eggs have the albumen, when coagulated by boiling, of a beautiful, opaque, milk-white substance, if they are quite fresh; but if not, it is a dirty or yellowish white, and not firm.

2065. *The yolk* has a mild and peculiar taste, and appears to consist of a deep yellow-coloured oil of the nature of fat oils, united to a portion of albumen sufficient to render it diffusible in cold water, in the form of an emulsion. It contains also a little sulphur and phosphorus, the former being evident from its blackening a silver spoon, the black stain arising from some of the silver uniting to the sulphur, and forming a sulphuret of silver, which is naturally of a black colour; consequently, this stain cannot be removed without rubbing off this part of the silver that has been altered. The use of the phosphorus is supposed to be in order to supply that principle to the bones of the young chick. The yolk is concrescible by heat, and becomes solid by boiling. It is employed as a medium for uniting resins and oils with water. The yolk is itself surrounded by an extremely thin membrane which separates it from the white.

2066. *The eggs of different birds vary much in size and colour.* Those of the ostrich are largest. One laid in the menagerie in Paris weighed two pounds fourteen ounces, held a pint, and was six inches deep: this is about the usual size of those brought from Africa. Travellers describe ostrich eggs as of an agreeable taste: they keep longer than hens' eggs. Drinking-cups are often made of the shell, which is very strong. The eggs of the turkey are almost as mild as those of the hen; that of the goose is large, but well-tasted. Ducks' eggs have a peculiar taste; the albumen is slightly transparent, or bluish, when set or coagulated by boiling, which requires less time than hens' eggs. Guinea-fowl eggs are smaller and more delicate than those of the hen.

2067. *The eggs of wild fowl* are generally coloured, often spotted, and the taste generally partakes somewhat of the flavour of the bird they belong to. Those of land birds that are eaten, as the plover, lapwing, ruff, &c., are in general much esteemed, but those of sea fowl have more or less of a strong fishy taste. The eggs of the turtle are very numerous; they consist of yolk only without shell, and are delicious.

2068. *As food, eggs are extremely nutritious.* The qualities of those belonging to different birds vary somewhat. Those of the common hen are most esteemed as delicate food, particularly when newly laid; the quality of the eggs depends much upon the food given to the hen. Eggs, in general, are considered as most easily digestible when little subjected to the art of cookery. The lightest way of dressing them is by poaching, which is effected by putting them for a minute into brisk boiling water; this coagulates the external white, without doing the inner part too much. Every one knows how much better they are when *newly laid* than for a day or two after they are laid. The usual time allotted for boiling eggs in the shell is three minutes, which should always be measured by a sand-glass. Less time than that in boiling water will not be sufficient to solidify the white; and more will make the yolk hard and less digestible; it is very difficult to guess accurately as to the time. Great care should be employed in putting them into the water, to prevent cracking the shell, which inevitably causes a portion of the white to exude, and lets water into the egg. They are often beaten up raw in nutritive beverages.

Eggs are employed in a very great many articles of cookery, entrées, entremets, and sucrés, and they form an essential ingredient in pastry, creams, flip, &c. It is particularly necessary that they should be quite fresh, as nothing is worse than stale eggs.

2069. *The metropolis is supplied with eggs* from all parts of the kingdom, and they are likewise largely imported from various places on the Continent, as France, Holland, Belgium, Guernsey, and Jersey. It appears from official statements mentioned in M'Culloch's "Commercial Dictionary," that the number imported from France alone amounts to about sixty millions a year; and supposing them, on an average, to cost four pence per dozen, it follows that we pay our continental neighbours above 83,000*l.* a year for eggs.

2070. *For the method of preserving eggs*, see Chap. III., Book X., "On the Preservation of Food."

CHAPTER VI.

FISH.

Sect. I.—general observations on fish.

2071. *In the ocean there appears to be an inexhaustible store of food in the finny tribes of animals.* Although in London fish is highly esteemed and considered rather as a luxury, yet in all countries where it is plentiful and cheap it is reckoned somewhat inferior in its nutritive powers to what is called butchers' meat. This is so well known, that the jockeys who ride at Newmarket, and who wish to weigh as little as possible, are never allowed to eat meat if fish can be obtained. The ancient Greeks seem to have looked upon fish in the same light, for we find in the Odyssey, Menelaus complaining that they had been obliged to live upon fish. Nevertheless, as the inhabitants of the seacoast in many parts of the world subsist almost entirely upon this kind of food, and enjoy perfect health, it is evidently, in general, sufficiently substantial. In Siberia, parts of Norway and Iceland, dried fish composes the principal part of the food of the inhabitants; and in Greenland and the Polar Seas the Esquimaux have no other. Being, however, less nutritive than meat, a larger quantity is necessary for sustenance. But though not so strengthening, it has some qualities which render it particularly valuable. Being less stimulating than butchers' meat, it occasions less febrile excitement, and being extremely tender and soluble, it is more easy of digestion; and though not sufficient, in all cases, to restore power to habits debilitated by disease, it is well suited for invalids, for inhabitants of towns, and for sedentary or studious persons.

2072. *Fish, however, like other animals, differ in some degree in their nutritive and other properties;* much, likewise, depends upon the modes in which they are prepared before they are employed as food. Like every other kind of aliment, it is preferable in its fresh state, but vast quantities are also salted, pickled, or dried, by which operations it is considerably altered in its properties.

2073. *Fishes may be separated into three great divisions* relatively to their habits, and the waters where they live. 1. Those which live entirely in the sea, hence called *salt-water fish*, as the cod and herring. 2. Those which live always in *fresh water*, as char, trout, &c. 3. Those which *migrate from the sea to the fresh water*, living alternately in each, as the salmon and sturgeon. Their natural history is a subject of great interest, but we can only touch upon such parts of it as bear upon their fitness for food; at the same time remarking that, as the article fish forms no inconsiderable figure on the table, the study of its good and bad qualities becomes a subject very deserving attention.

2074. *Fishes present considerable variety in the structure and firmness of their muscles.* The muscles of some fish resemble flesh, as that of the whale, shark, and sturgeon: of others it is white, and disposed in flakes, as in the cod and the haddock; and in others, again, it is fibrous, as in flat fish and eels. In general, the muscular part is less firm than that of land animals; in some it is comparatively dry; in some, soft and gelatinous; and in others fat and oily. The fat or oil is sometimes disposed between the layers of the flesh, as in salmon, or it is dispersed through the flesh, as in eels, herrings, sprats, &c. In the cod a curdy matter, resembling coagulated albumen, appears between the flakes of the flesh when fish perfectly fresh is cooked; this disappearing entirely when the fish is stale, furnishes a good test of its condition: the fat or oil of cod resides only in the liver. Flat fish and eels have none of this curdy matter, the flesh not being in flakes. All the livers of fish abound in oil. Fish having much fat or oil mingled with their muscles are less digestible than those which are leaner, but they are more nutritive, as, for instance, salmon, eels, and herring. Some of the cartilaginous fish, as skate, are also extremely nutritive.

2075. *Some fish are said to be poisonous*, but these reside chiefly in the tropical seas, and never visit our coasts.

2076. *The flavour of fish*, like that of other animals, is influenced in a certain degree by the nature of their food, and on this account the same species of fish will vary somewhat in its flavour on different coasts, and in different lakes and rivers. Some fish improve in firmness and flavour as they attain a certain age, as cod and haddock; but generally when they become old they get coarse.

2077. *The season of the year has the most decided influence upon the quality of fish*, as connected with the time of their spawning. Fish, in general, are in the best condition before they spawn, and many while they are full of roe, as the smelt, pouting, mackerel, and sole; but it is universally the case, that immediately when the spawning is over they are "out of season" and unfit for food: sometimes, indeed, at this time fish are unwholesome. This circumstance is of so much importance, that it has been considered a fit subject for the interference of the legislature, which regulates the times during which only certain fish may be caught. When fish are in season the muscles are firm, and they boil white and curdy; but when they appear transparent and bluish, though sufficiently boiled, it is a sign that the fish is not in season, or is not fresh.

Previous to the approach of the spawning season, there is a natural preparation necessary to enable the fish to undergo the fatigues and fastings by which it is accompanied. The muscles acquire size and strength, especially those connected with the tail, the principal organ of progressive motion, so that the body behind appears plump and round. A great deal of fat is deposited between the muscles, but especially on the belly, the flesh of which is, at this time, of considerable thickness. As the spawn advances to maturity, the fat is withdrawn for its nourishment, the belly becomes little else than skin, and while the epicure, upon seeing the large roe, imagines that his fish is in the best condition, it has nearly reached the maximum of its worthlessness When the business of spawning is over, the leanness of the fish then becomes apparent, and the extraordinary muscular exhaustion which it has undergone is marked by the thinness of its head and the lankness of its tail.

It appears, however, the same species of fish is occasionally subject to variations in the periods of spawning, which explains the reason why sometimes a fish is found quite good as food, while the rest of the species is poor and inedible. This is the case with cod, and also flat fish. The summer and autumn are the seasons most favourable for the procuring of fish in general, but on account of the various seasons for spawning, no month is without a supply of some particular species.

2078. *Fish surpass in fecundity all other animals used as food.* In the roe of the sturgeon above a million and a half of ova have been counted; in the mackerel, 129,000; in the perch, 69,000; in the carp, 167,000; and in the pike, 166,000.

2079. *Every part of fish may be eaten with safety,* with the exception of those that are poisonous. The hard roe, or that of the female, is particularly nutritious, often large, and forms an excellent food. Caviare is the prepared roe of the sturgeon.

2080. *Naturalists have divided fishes into two great tribes, the osseous and the cartilaginous,* according to the bones. In the first, the bones are more or less hard and firm, and contain a great deal of phosphate of lime, as in the cod and ling; in the latter the bones are soft, and consist only of cartilage, as in the skate. This distinction, however, is not precise, for osseous fishes have a great deal of cartilage, and some of the cartilaginous fishes possess a small portion of calcareous matter in their bones. Nor is the composition of the bones uniform, some having more phosphate of lime than others Some fish are very gelatinous, as eels, and make excellent soup.

2081. *The skin of most fishes is covered with scales;* but some are almost without, these being very minute, as the eel. The thickness of the skin varies according to the strength of the scales; it is, accordingly, very thick in skate, eels, &c., and thin in those species that possess larger scales, as the carp and bream; hence, in preparing these fish for the table, the former are deprived of their skin, and the latter only of their scales. The surface of the skin of fishes is more or less covered with a slimy, gelatinous, or mucous substance of a peculiar nature, secreted by an apparatus for the purpose, and shed upon the skin by a number of minute ducts or openings: this is a defensive secretion against the friction and washing of the water; but the integument that affords the chief defence to the skin are the scales. Those fish that want scales, or have them very small, have more of the slimy matter, as in eels. Dr. Paris states that the pulpy, gelatinous skin of the turbot, and the glutinous parts about the head of the cod, though highly prized by gastronomes, are very apt to disagree with invalids.

2082. *Little attention is paid to the mode of killing fish,* as the object is to keep them alive as long as possible; but many of them die as soon as they are taken out of the water. The Dutch take great care to bring them alive to market, and those that die are sold at an inferior price; but though this ensures their being fresh, yet, when they are kept long alive, the fish become exhausted, and are worse in quality than if they had been killed when caught, and kept only the proper time: when preserved in the wells of ships, they are frequently rendered poor. Fish, in general, are extremely voracious, the greater number being carnivorous, feeding upon each other, the greater on the smaller; thus the cod pursues the whiting; but some fish live upon marine plants.

2083. *White fish,* whose muscles are the firmest and least oily and viscid, possess the most valuable qualities as food, and are, in particular, the best calculated for invalids. These, comprehending the cod, ling, tusk, coalfish, haddock, and whitings; also the flat fish, as turbot, skate, soles, and flounders, swarm about the British shores, and particularly in the whole northern sea, from the Dogger Bank, in lat. 54°, to the northern extremity of Iceland, in lat. 67°; from the coast of Norway eastward to an unknown distance on the west, may be considered as one great fishery, in which Scotland, as lying in the centre, has a manifest advantage over all other nations. The number of friths and inlets of the sea, on the west coast of Scotland, render that country peculiarly favourable for the prosecution of fisheries.

The muscles of the red-coloured fish, as salmon, trout, &c., are of a peculiar tint, which has acquired the name of salmon colour, and the fish are generally esteemed in proportion to the height of this colour. They are always more or less of a fat or oily nature.

2084. *Flat fish* are called by naturalists *Pleuronectidæ.* They have no swimming bladder, and therefore keep close at the bottom. Both eyes are on one side, and that side is uppermost: when disturbed, they sometimes make a rapid shoot, changing their position from the horizontal to the vertical, but they soon settle down again into their former position.

Mr. Yarrell observes that those fishes which swim at the bottom of the sea are so constructed as to consume but a small quantity of oxygen, and have their blood only two or three degrees warmer than the temperature of the water at the surface; but they have a high degree of muscular irritability; they retain life long after they are taken out of the water, and their flesh remains good for several days. Various flat fish, and the eel, are seen gaping and writhing on the stalls of the fishmongers for hours in succession. On the contrary, those fish which usually swim near the surface of the water have a high degree of respiration, and their blood has a warmer temperature, which, in the case of the Bonito, amounts to 90° when the water is 80°. These have little irritability, and generally die as soon as they are taken out of the water, which is also the case with the mackerel, salmon, trout, and herring. In consequence of this, the latter class of fishes soon decompose or spoil after they are killed; and, to be in perfection, should be prepared for the table the day they are caught; whereas turbot is better for being kept a day or two, since they are tough while any irritability exists.

2085. *The mode of cooking fish considerably affects their properties as food.* Plain boiling, baking, and roasting appear to be the methods that prepare it in the fittest manner. There appears no reason why stewing should be objectionable, except that it is usually accompanied by numerous additions that render it extremely indigestible, for instance, port wine. The various sauces commonly eaten with fish are probably the cause of most of the faults laid to the charge of this useful aliment; these sauces are to be suspected, when purchased, as we cannot at all times be certain of their composition; and it is well known that they are sometimes deleterious. The observation which we have often made applies here in a particular manner, namely, that it is of the first importance we should *know* what we eat and drink. Few species of vegetables appear to be eaten with fish. Potatoes and parsnips are the principal of those which are found by experience to agree well.

2086. *A process called crimping is sometimes adopted for the purpose of improving cod and some other fish.* Sir Anthony Carlisle has investigated the change thus produced, and we are indebted to him for some curious observations upon the subject. Whenever the rigid contraction has not taken place, the process may be practised with success. The sea fish destined for crimping are usually struck on the head when caught, which, it is said, protracts the term of its irritability; and the muscles which retain this property longest are those about the head. Many transverse sections of the muscles being made, and the fish immersed in cold water, the contractions caused by this crimping take place in about five minutes; but if the mass be large, it often requires thirty minutes to complete the process, which is for the purpose of giving firmness to the fish. It has been found that the muscles subjected to this process have both their absolute weight and specific gravity increased; whence it appears that water is absorbed, and condensation is produced. This operation improves the flavour, as well as the digestibility of the fish.

2087. *The blowing of fish* is a fraudulent practice sometimes employed by fishmongers, of a similar nature to the blowing of flesh and poultry. It is performed especially on cod and whitings, by introducing the end of a quill or tobacco pipe at the vent, and blowing through a hole made with a pin under the fin which is next the gill; thus making the fish appear to the eye full and large, though, when dressed, it will be very different. This imposition may be easily detected, by placing the finger and thumb on each side of the vent, and squeezing it pretty hard, for the air will then be perceived to escape, and the fish will shrink into its natural dimensions.

2088. *The migration of various species of fish* in shoals, and almost infinite multitudes, to particular coasts at certain times of the year, is a circumstance of great advantage to mankind, as it gives an opportunity of taking them with ease, and in vast quantities. The causes that induce fish to make these periodical movements are stated to be the instinct they possess for seeking suitable situations to deposite their spawn, and their search after a supply of food. Several kinds of fish, as the cod, haddock, mackerel, and herring, annually leave the deeper and less accessible parts of the ocean, the region of the zoophytic tribes upon which they prey, and approach the shallow shores to deposite their spawn within that zone of marine vegetation which fringes our coasts, extending from near the high-water mark of neap tides to a short distance below the low-water mark of spring tides. Amid the shelter of this region, afforded by the groves of arborescent fuci, the young fry come to life and spend their infancy in a situation where numerous small animals reside, and which constitute their most suitable food; and it is said that since these marine plants have been cut down on many of the coasts for the manufacture of kelp, the fisheries have suffered in consequence. Even the finny tr... inhabiting lakes, as the gwinead, and other species, periodically leave the deep water, and, in obedience to a similar law, come near to the margin to deposite their spawn.

2089. Many species of fish, as the salmon, smelt, and others, in forsaking the deep water, and approaching a suitable spawning station, leave the sea altogether for a time, ascend the rivers and their tributary streams, and, having deposited their eggs, return again to their usual haunts. With respect to the migration of herrings, see "Herring," Subsection 21.

2090. *Though it is generally supposed that fish which do not migrate from salt water to fresh,* and which are properly fish of the sea, will not live in fresh water, yet, from some interesting and successful experiments which have been made, it appears that several species of fish decidedly marine may be preserved alive a long time in fresh-water ponds, and that they even thrive and get fat in them. Some very curious observations on this subject have been published by Dr. Macculloch in the *Journal of the Royal Institution*, Nos. 32 and 34, and in the *Edinburgh Review*, 1822.

This capability of some salt-water fish to live in fresh water has long been known in Sicily, where a species of mullet, when taken from the sea, are by the fishermen thrown into the Lake Linterni, where they are kept for use, and where they increase in size and improve in flavour: this lake has no communication with the sea.

2091. *An account of the naturalization of sea fishes in a lake* was lately read at a meeting of the Zoological Society by Mr. J. B. Arnold, of Guernsey. The area of the lake is about five acres; its depth varies, and its bottom is muddy, gravelly, and rocky. The water during nine months of the year is drinkable for cattle, but, in consequence of a supply which it receives through a tunnel communicating with the sea, is rather salt in summer, at which season the freshets do not come down so plentifully as at other times. Several salt-water fish were introduced into it, as turbot, sole, plaice, brill, smelt, gray mullet, whiting, pilchard, bass, and gray roach. All these thrive well, and are believed to have increased in numbers. The gray mullet, in particular, has bred as freely as in the sea. A single whiting, that had been caught three successive years, was found to have grown considerably. Pilchards also throve remarkably well. It is even suspected that hybrid fishes have been produced, as several have been caught which were unknown to persons well acquainted with the species annually met with on the coast of Guernsey. Some of these sea fishes, after having been naturalized in this lake, have been transferred to ponds of spring water, where they have not only lived, but done well; and such naturalized fish have been carried to a long distance, being much more tenacious of life than those caught in the sea.

2092. *The preservation of sea fish in salt-water ponds* is so obvious an idea, that it is surprising to find it so little practised in England; nor is it much known on the Continent. In Scotland, however, this has been tried with success in several places. One of the largest and best of these belongs to Macdonnel, of Leggan, in Wigtonshire, which has been in existence upward of thirty years. This pond is stocked with turbot, cod, haddock, whiting, thornback, coalfish, and salmon. It is stated, also, that the same mode is practised in Todness Island, in Essex, where it answers perfectly well. From these and similar facts, it would appear to be extremely possible to preserve fish for the market in enclosures or ponds made in the mouths of rivers, estuaries, or in the sea, so that a uniform and regular supply of fish might be obtained in all weathers.

2093. *Fresh-water fish are frequently preserved and bred in ponds*; but the abundance of salt-water fish in this country renders those of lakes and ponds comparatively of small importance. Char and trout abound in some lakes, as at Keswick and Loch Lomond; but these fisheries are little attended to. Fish-ponds are most plentiful in the counties of Surrey and Berkshire, and are sometimes let to dealers in carp and other pond fish; but the breeding and fattening fish for the market is much less studied here than on the Continent, where the Roman Catholic religion causes this kind of diet to be more in demand at all seasons. In China this practice is carried to a great extent. The fish most usually kept in ponds are carp, tench, perch, gudgeon, eel, and pike.

All the fresh-water fish are taken occasionally, and most of them solely by the rod and line. The art of angling is more generally practised for amusement than profit; but it is a sport of great antiquity, and is followed with the greatest avidity by persons of every rank in life. It has some advantages over other rural sports; it is but little dangerous, and incurs small expense, and is peculiarly fitted for the placid and thoughtful; accordingly, we find that some men of great eminence have been much attached to it, as affording a relaxation from deep study, and the opportunity of contemplating nature. We may refer, on this subject, to the well-known "Salmonia, or Days of Fly Fishing," written by one of the greatest philosophers of modern times, Sir Humphrey Davy. The laws have ever been favourable to this pursuit, protecting the fish, and the authorized fisher, and punishing the depredations of the poacher. Proprietors of grounds through which rivers or streams pass have the exclusive right of fishing in them, and trespass is punished by fine. The proper season for angling is from the spring to the autumn. The different fish frequent different places, and require various kinds of bait or artificial flies, the study of which, with the numerous circumstances connected with it, will be found in works written "on angling."

2094. *A method of increasing the quantity of trout in rivers or lakes to almost any extent* is mentioned by Sir H. Davy in his "Salmonia," and which he states has been practised by M. Jacobi, a German gentleman.

"His plan of raising trout from the egg was a very simple one. He had a box made with a small wire grating at one end in the cover, for admitting water from a fresh source or stream, and at the other end of the box there were a number of holes to permit the exit of the water; the bottom of the box was filled with pebbles and gravel of different sizes, which were kept in water that was always in motion. In November, or the beginning of December, when the trout were in full maturity for spawning, and collected in the rivers for this purpose upon beds of gravel, he caught males and females in a net, and, by the pressure of his hands, received the ova in a basin of water, and suffered the melt to pass into the basin; in a few minutes he introduced them upon the gravel in the box, which was placed under a source of fresh, cool, and pure water. In a few weeks the eggs burst, and the box was filled with an immense number of young trout, which had a small bag attached to the lower part of their body, containing a part of the yolk of the egg, which was still their nourishment. In this state they were easily carried from place to place in confined portions of fresh water for some days, requiring, apparently, no food; but after about a week, the nourishment in their bag being exhausted, they began to seek their food in the water, and rapidly increased in size. It is said that the experiment succeeds also with the melts of mature fish that had been just killed, if they are mixed together in cold water immediately after they are taken out of the body. One great advantage of this method is, that by this means the young ones are preserved from the attacks of fishes, and other voracious animals and insects, at the time when they are perfectly helpless and most easily destroyed. The same plan would no doubt answer equally well with grayling, or other varieties of the salmo genus. But, in all experiments of this kind, the great principle is to have a constant current of fresh and aërated water running over the eggs. The uniform supply of air to the fœtus in the egg is essential for its life and growth, and such eggs as are not supplied with water saturated with air are unproductive. The experimenter must be guided exactly by the instinct of the parent fishes, who take care to deposite the impregnated eggs that are to produce their offspring only in sources continually abounding in fresh and aërated water. It appears that the leaves of plants that grow in water afford a continual supply of oxygen to the water, and that many fish possess the instinct to deposite their eggs upon these leaves, a circumstance that affords an easy opportunity of making observations upon the growth of young fish, as the leaves with the ova may be kept in a vessel of water. The same observations will apply to fishes of the sea."

2095. *The art of carrying and keeping fish*, as we are informed by Sir H. Davy, is better understood on the Continent than in England. "In Austria every inn has a box containing grayling, trout, carp, or char, into which water from a spring runs, and no one thinks of carrying or sending *dead* fish for a dinner. A fish barrel full of cool water, which is replenished at every fresh source among these mountains, is carried on the shoulders of the fisherman: and the fish, when confined in wells, are fed with bullocks' liver cut into fine pieces, so that they are often in better season in the tank or stew than when they are taken." Sir Humphrey has "seen trout, grayling, and char even, feed voraciously, and take their food almost from the hand. These methods of carrying and preserving fish have been adopted from the monastic establishments. At Admont, in Styria, attached to the magnificent monastery of that name, are abundant ponds and reservoirs for every species of fresh-water fish; and the char, grayling, and trout are preserved in different waters, covered, enclosed, and under lock and key." Some remnants of the same practice may be seen in the colleges of Cambridge.

Since England became a Protestant country, the cultivation of fresh-water fish has been neglected; but the formation of fish-ponds in hilly or mountainous districts would be a matter of little difficulty, and by this means a considerable addition might be made to the food of these places.

2096. *In China, the art of preserving and fattening fish* is carried to a high degree of perfection. An account of the method used in that country, quoted in the *Quart. Journ. of Science*, is deserving of notice. In the district round Canton numerous fish-tanks are dug in the ground. When the pond is finished, and filled with water, the owner goes to market, and buys as many young store-fish as his pond can conveniently hold; this he can easily do, as almost all their fish are brought to market alive. Placed in the pond, they are regularly fed morning and evening, or as often as the feeder finds necessary. Their food is chiefly boiled rice, to which is added the blood of any animals they may kill, wash from their stew-pots and dishes, &c.; indeed, any animal offal or vegetable matter which the fish will eat. Fish so fed and treated advance in size rapidly, though not to any great weight, as the kind (a species of perch) which came under our observation never arrive at much more than a pound avoirdupois; but from the length of three or four inches, when first put in, they grow to from eight to nine in a few months, and are then marketable. Draughts from the pond are then occasionally made; the largest are first taken off, and conveyed in large, shallow tubs of water to market; if sold, well; if not, they are brought back, and replaced in the pond until they can be disposed of. The business of fish-feeding is so managed that the stock are all fattened off about the time that the water is most wanted for the garden crops. The pond is then cleaned out, and the mud carefully saved, or spread out as manure, again filled with water, stocked with young fry, and fed as before. This mode of employing the ground was considered in that country as more profitable than any other.

2097. *The Chinese, likewise, propagate fish* by collecting the spawn in the rivers and lakes where it is deposited, and conveying it in vessels of water to their fish-ponds; this water with spawn is regularly sold by merchants, who make a trade of transporting it from one province to another. It is even said that these ingenious people have a method of hatching the spawn of fish. They fill the shell of a new-laid egg with the gelatinous matter that contains the spawn, wax up the hole through which it was introduced, and put the egg under a sitting hen. At the expiration of a certain number of days they break the shell in water warmed by the sun. The fry are then found hatched, and are kept in pure fresh water till they are large enough to be thrown into the pond with the old fish.

Lately, an account has been published of successful experiments of the same kind having been made by Sir Francis Mackenzie, of Coram-house, Scotland, and others who have reared salmon and trout from spawn taken from the fish, and deposited in beds of gravel laid in ponds; and it is stated by Professor Agassiz that the *ova* of fish, when properly impregnated, may be conveyed in water of a proper temperature, even across the Atlantic, as safely as if it were naturally deposited by the parent fish.

2098. *The term shell-fish*, though still retained in popular language, is not at present employed by naturalists. It includes the *Crustaceæ*, or crustaceous animals, as lobsters, crabs, shrimps, &c., and the *Molluscæ*, or soft animals. Of the Molluscæ, some are covered with a hard outer shell, in one or two pieces, and are named univalves, as the periwinkle, or bivalves, as the oyster; or they are entirely naked, having no shell, as the Medusæ, Sepia, &c. The Crustaceæ contain numerous species and varieties in different parts of the world; but we have only a few in our seas. Animals with shells abound with us, but only a few are large enough to be worth eating. Of the naked Molluscæ none are used in this country as food, though the Sepia or cuttle-fish is eaten in the south of France.

Most shells consist entirely of carbonate of lime (the same as chalk), connected together in layers with a little animal matter resembling albumen; hence shells will burn to a very pure lime. The interiors of many shells are lined with a pearly matter called *nacre*, which is sometimes extremely beautiful, particularly in mother-of-pearl. Pearls, which are found in certain shells, are nothing more than concretions of this substance, which is also carbonate of lime.

2099. *It is said that living too much upon fish* is apt to give rise to cutaneous eruptions; and this Dr. Paris considers as not improbable, particularly in hot climates. The oily principle upon which the odour of fish depends is absorbed into the blood, when this kind of food is taken, as is evident from the peculiar flavour of sea-fowl that live upon fish. Even the hogs that, in Cornwall, have access to pilchard have often a fishy flavour: and from the sympathy between the stomach and the skin, it is not unlikely that the oily fat fish may have a tendency to produce cutaneous derangement. Thus many facts appear to point out the propriety of changing our food occasionally. It has been conjectured that the priests of Egypt were prohibited from eating fish to avert the leprosy, which was supposed to be induced by living too much upon it; in the same manner that it is thought the Jewish legislator interdicted the use of pork from his belief in its unwholesomeness.

2100. *The supply of fish in the seas round Britain* is not only abundant, but inexhaustible; and yet, notwithstanding this, and the encouragement given by government, the fisheries have not proved so profitable as might have been expected. There is little fish consumed in the interior of the kingdom; and though in London immense quantities are annually made use of, "there can be no doubt," observes Mr. M'Culloch, in his valuable Dictionary of Commerce, "that the consumption would be much greater were it not for the abuses in the trade, which render the supply comparatively scarce, and, in most instances, exceedingly dear." "That this harvest," says Mr. Barrow, "ripe for gathering at all seasons of the year, without the difficulty of tillage, without expense of seed or manure, without the payment of rent and taxes, is inexhaustible, the extraordinary fecundity of the most valuable kinds of fish would alone afford abundant proof. To enumerate the thousands, and even millions, of eggs which are impregnated in the herring, the cod, the ling, and, indeed, in almost the whole of the esculent fish, would give but an inadequate idea of the prodigious multitudes in which they flock to our shores; the shoals themselves must be seen in order to convey to the mind any just notion of their aggregate mass." As the fisheries, and the various circumstances connected with them, are managed at present, the supply of fish is extremely uncertain, which causes a glut at one time, while at another there is scarcely any to be had. The cause of this is obvious. Fish are extremely changeable in their places of resort, and they will leave their accustomed haunts for long periods without our being able to ascertain the reason; nor do we know all the causes of their migration. Fish also require great care in packing and transportation, as they soon spoil. So far it is easy to perceive some of the physical difficulties over which we have no control. But still a question remains, whether all the means are employed which might enable us to enjoy all the advantages of our insular situation, and the abundance with which we are surrounded. But already we see reason to hope that the time is not far distant when the modern improvements will extend to this subject. Before steam navigation, a large proportion of the salmon sold in the London market could not have been brought fresh, and a contrary wind frequently rendered a cargo unfit for sale. By the railways fresh fish will be conveyed daily to inland towns which now receive a supply only two or three times a week, or less frequently. Already the inhabitants of Birmingham have benefited in this respect by the Grand Junction Railway, which gives them access to the Liverpool fish market, and salmon brought to London from Scotland by the steam vessels have reached that place by the same railway. The want of inland conveyances has hitherto deprived the country of the advantage of the extraordinary quantities of fish that have been occasionally caught. Even of cod-fish one ton and a quarter have been taken at a time in one boat. Of mackerel the haul has been sometimes so great that it could scarcely be disposed of, and pilchards and sprats are often obliged to be used as manure for want of sale. The means of conveying these to inland districts must produce, at times, a seasonable supply of food in future.

Sect. II.—salt-water fish.

Subsect. 1.—*The Turbot* (*Pleuronectes Maximus*, Linn.).

2101. This is the most highly prized of our flat fish. It inhabits the northern and Mediterranean seas, and is taken on the south coast of England in great plenty. It grows to a large size, sometimes even to weigh thirty pounds. The flesh is white, firm, rich, gelatinous, and of a fine flavour; but being a ground fish, Ude, the celebrated French cook, says that it is better for keeping a day or two, since, when just caught, it is apt to be not merely firm, but a little too hard. They are often brought to London alive in well-boats, and, as they do not all spawn at the same time, some are in season in every part of the year. The London market is chiefly supplied by the Dutch fishermen, and a preference is given to those caught on the coast of Holland; but a great many are likewise taken at the Dogger Bank, and on the coasts of Cornwall and Devon. Those sent up from Scotland packed in ice are very inferior, and may be purchased for a fourth of the price given for the best turbots. From the great demand for this esteemed fish, notwithstanding its price, vast numbers are brought to London, so many as 87,958 in one year.

Subsect. 2.—*The Sole* (*Pleuronectes Solea*, Linn.).

2102. The sole is well known to be, next to the turbot, the best of our flat fish. It inhabits the sandy bottom on all our coasts, but is finer in the west and south than in the north and east. It is an inhabitant of the northern seas, the Baltic, Mediterranean, and America. Great numbers are taken on the south coast of England by the boats from Dover, Folkestone, Brighton, and Hastings, and brought to the London market alive by well-boats or by land carriage. The finest are caught off Plymouth and in Torbay; they frequently weigh eight or ten pounds per pair, and have been seen two feet in length, but the smaller are preferred. They are likewise taken off Yarmouth. They are full of roe at the latter end of February; for a few weeks after, they are soft and watery, but they soon recover. Some of them are in season all the year round; but they are in highest perfection about midsummer. As they are an excellent, firm, white, and delicate fish, they are frequently seen upon the London tables. It is essential that they should be perfectly fresh, or the flesh loses its firmness, and thickness is desirable. Those from the deep water are superior in quality. They have been kept alive in fresh-water ponds; in Mr. Arnold's pond in Guernsey, the sole becomes twice as thick as one of the same length from the sea, and they are known to breed there. They are taken also in the Arun in Sussex, five miles from the sea, where they remain all winter, burying themselves in the mud.

SUBSECT. 3.—*The Brill* (*Pleuronectes Rhombus*, Linn.).

2103. This is somewhat like the sole, but broader, and is intermediate between that and the turbot. It is a fine fish, and, when large, not much inferior to the latter, though much cheaper. It is brought in abundance to the London market.

SUBSECT. 4.—*The Flounder* (*Pleuronectes Flesis*, Linn.).

2104. The flounder is generally the least esteemed of our flat fish. It is smaller than the plaice. It inhabits both the seas and rivers, coming into the latter to breed; and they will thrive in fresh-water ponds. It is very abundant on our coasts, and they also frequent our rivers at a considerable distance from the salt water. Great quantities of them are brought to the London market, and are sold at a cheap rate. They are in season from January to March, and from July to September. It is considered as a light food, being sweet and easy of digestion. The Thames flounder is a delicate and esteemed fish.

SUBSECT. 5.—*The Dab* (*Pleuronectes Limanda*, Linn.).

2105. This is very similar to the flounder, but smaller and thinner. It is out of season in May and June.

SUBSECT. 6.—*The Plaice* (*Pleuronectes Platissa*, Linn.).

2106. This flat fish is extremely abundant on our coasts, and is also found in the Mediterranean and the Baltic. It is inferior to the sole, the flesh being less firm and white, and not so well flavoured; but when they are of a large size, and just caught, they are by no means despicable. They are sold at a low price, and are generally purchased by the poorer people. The best of those brought to the London market are called *Dowers plaice*, being chiefly caught in the Dowers, or on the flats in the sea between Folkestone and Hastings, weighing from one to five and six pounds. On the coast of Holland they are obtained considerably larger, and are known here as *Dutch* plaice; some of them have been even eighteen pounds. Like all ground fish, they are very tenacious of life, and therefore keep well.

SUBSECT. 7.—*Halibut* (*Pleuronectes Hippoglossus*, Linn.).

2107. This is the largest of our flat fish, being sometimes found of the weight of two or three hundred pounds, and in the seas of Iceland and Newfoundland much larger. Its flesh is extremely white, and, when small, they are thought by some to be nearly as fine as turbot; but when they are large, the flesh is coarse and dry, and is not much esteemed, having little flavour. In some parts of Scotland this is called the turbot, which often occasions mistakes with the English people. In the London market it appears in March and April, and its flesh is sold in slices by the pound at a low price.

SUBSECT. 8.—*The common Cod* (*Gadus Morhua*, Linn.).

2108. This is one of the most important of the finny tribe, from the excellence of the food which it supplies, and its prodigious abundance. It is an ocean fish, confined to cold climates, and found only in the northern parts of the world. It is supposed to reside chiefly between the latitudes of 66° and 45°. Those taken north and south of these latitudes are either few in number, or bad in quality. As far north as Greenland they are small and emaciated; and they do not reach so far south as the Mediterranean, where they are unknown. The great resort of this fish is on the banks of Newfoundland, and the other sand-banks that lie off the coast of Cape Breton, Nova Scotia, and New-England, where they find food in the worms produced in these sandy bottoms. They are also taken on the south and west coasts of Iceland, on the coasts of Norway, in the Balti·, and off the Orkneys and western islands of Scotland. The principal fish eries whicl. at present supply the London market with fresh cod are hollows between the Dogger Bank, the Well Bank, and Cromer on the east coast of England. The fish caught there separates, when cut, in fine large flakes; it is brought alive to London in well-boats. The fishermen seldom find any cod or other round fish on the bank itself, but upon the sloping edges and hollows contiguous to it. The shifting sand on the top of the bank affords them no subsistence; and the shallow agitated water allows them no rest. Inhabiting deep water, they are taken only with lines and hooks. A great deal is caught off Scarborough. They are also taken in great plenty on the coast of Scotland, and the northeast coast of Ireland.

Mr. Yarrell, in his "History of British Fishes," mentions the two principal varieties of cod in the market as *Dogger Bank* and *Scotch* cod. The first has a sharp nose, with the body of a dark-brown colour; the second has a round nose, and the body of a light yellowish ash-green. The first is most esteemed.

2109. *In our seas the cod-fish begins to spawn* in December, and they continue to deposite their eggs on rough, rocky ground till the end of February, when they become poor. Some continue in the roe till the beginning of April: they are, therefore, a winter fish, being in high season about Christmas. They recover from their spawning sooner than any other fish, and it is common to take some cod all the summer. They are amazingly prolific. Leewenhoek counted several millions of eggs in the roe of one cod-fish of middling size, a degree of increase that must render them inexhaustible by human means. They are in highest perfection in the winter, and they keep well; but the glutinous parts about the head, so highly prized by gastronomes, lose their delicate flavour after the fish has been twenty-four hours out of the water. The cod is sometimes found of a very large size, weighing as much as sixty pounds; thirty pounds is not uncommon, but twenty-five pounds is the usual size of a well-conditioned fish; about six or eight pounds is the best for the table; but they are taken of all sizes from that to one pound. When below a pound, they are called *codlings;* the smaller ones are apt to be soft and watery. They are selected by their plumpness and roundness, especially near the tail; by the depth of the pit behind the head; and by the regular appearance of the sides, as if they were ribbed.

2110. The cod is particularly firm and rich when in season, which is known by layers of white curdy matter between its flakes when boiled. It is likewise extremely nutritious and light. When just killed, and in season, the gills are red, the neck thick, the flesh firm, and the eyes bright. The firmness of the fish is much improved by *crimping*. The *milt* of the cod, or soft roe, is brought to table as a garnish, but, from its oily nature, is not fit for delicate stomachs.

2111. *What is called the sound in cod-fish* is the air-bladder, or swimming-bladder, by means of which the fish is enabled to rise or sink in the water. The fish has the power of compressing this bladder; and then the air within it is condensed, in consequence of which its specific gravity, and, therefore, that of the whole fish, becomes heavier than water, and the fish sinks; when it desires to rise, by relaxing the muscles connected with this bladder, it suffers the air within it to be expanded, and the fish becomes specifically lighter than the water, and ascends. The sole, flounder, and other flat fish, have no bladder, and are therefore always at the bottom.

2112. *Cod is brought from the Dogger Bank and other places, and kept alive in the well-boats, or store-boats,* some stout vessels, of eighty or a hundred tons burden, having a large tank for preserving the fish alive. These boats remain as low as Gravesend, because the water there is sufficiently salt; if they come higher up, the fresh water would kill the fish; from the store-boats a portion is sent to Billingsgate by each night tide.

2113. *Cod has been kept in salt-water ponds* in different parts of Scotland, and found to maintain their condition unimpaired. Of these ponds, there is one in Galloway, another in Fife, and a third at Orkney. In these preserves the fish is regularly fed, and sometimes take the food from the hand.

Vast quantities of cod are taken on the Banks of Newfoundland, and brought to us, salted, for an account of which, as well as the other methods of curing fish, by drying, smoking, and pickling, see Book X., "Preservation of Food." By all these methods of curing fish, the digestibility is much impaired, and they are rendered unfit for invalids.

Subsect. 9.—*The Haddock* (*Gadus Æglifinus*, Linn.).

2114. This fish is an inhabitant of the northern seas of Europe; but it is remarkable that it does not enter the Baltic, and is not known in the Mediterranean. It appears on our coasts in December, and is then full of roe. Some are in season from August to February. The haddock resembles the cod in some of its properties. The small ones, when boiled, are less firm than the cod, and rather watery, but the larger fish are firm, and of a fine flavour. In general, they do not exceed the height of ten or twelve inches, weighing two or three pounds, but they are known sometimes to grow to the size of three feet: when large, they are coarse. They are better for being hung up for a day or two, with a sprinkling of salt. They are sometimes cured with salt, and dried; and this is done particularly well at the fishing village of Findhorn, near Aberdeen, by hanging them a day or two in the smoke of peat. *Finnan haddocks* (a corruption of Findhorn), broiled, are much used at breakfast by the Scotch, and are esteemed a great delicacy. An imitation of these, it is said, may be made by laying the fish in salt for two hours, letting the water drain from them, and then washing them over with pyroligneous acid, and, lastly, hanging them in a dry place for a few days.

Haddocks have been kept in salt-water ponds, or preserves, and will become so tame as to feed from the hand. They are in season during the last three months of the year.

SUBSECT. 10.—*The Whiting* (*Gadus Merlangus*, Linn.).

2115. This fish is tender, delicate, extremely light, and easy of digestion; perhaps the most so of any of our salt-water fish. Whitings appear in large shoals in our seas in the spring, keeping at the distance of about half a mile to that of three miles from the shore, where they appear to come to deposite their spawn. They are taken by the line. Their usual length with us is ten or twelve inches, and they seldom exceed a pound and a half in weight; but on the edge of the Dogger Bank they are found to weigh from four to eight pounds. They are in highest season during the first two months of the year, though they are occasionally taken all the year round. They are not allowed to be caught when less than six inches in length. The spawning season extends from March to September, and towards the end of the year they recover and become good.

In Cornwall, whitings are salted and dried, and in winter sold in the markets under the name of "Buckhorn."

2116. *The whiting pout* (*Gadus luxus*, Linn.) is common about the mouth of the Thames, and generally all round our coasts; it is caught also in the northern seas. It much resembles our whiting, and is an excellent fish. It is most in season in November and December.

2117. *The whiting pollach* (*Gadus pollachius*, Linn.) is caught all round our coasts, and is very common; being somewhat like the whiting, it is sometimes mistaken by the inexperienced for that fish. Its flesh is delicate.

SUBSECT. 11.—*The Ling* (*Gadus Milva*, Linn.).

2118. This fish is an inhabitant of the northern seas, and but little used in Britain as food. The ling in form nearly resembles the cod, but is more slender, and grows to the length of six or seven feet. It is taken in vast quantities off the Orkney, Shetland, and Western Isles, and is found also near the Scilly Isles, and off Flamborough Head. It only inhabits deep water. It is in perfection from February to the end of May; and they spawn in June, depositing their ova in the soft bottom. When they are less than twenty-six inches in length, they are called *drizzles* on the Yorkshire coast, and are consumed at home, being an excellent fish; but when larger they are coarse: they are salted, dried, and exported to Spain and the more southern parts of Europe, where the ling does not inhabit. The sounds and roes are salted separately; and a good deal of oil is obtained from the livers, as well as from those of the cod.

SUBSECT. 12.—*The Torsk, or Tusk* (*Gadus Brosme*, Linn.).

2119. This fish is extremely abundant in the Shetland Islands, where it is called *tusk*. It is a northern fish, found also in Norway and Iceland; but it comes no farther south than the Orkneys, where it is scarce. When fresh, the flesh is hard, and the fish are generally dried, like stockfish, without salt: when soaked in water, and boiled, they constitute the food of a numerous population in the North; but in this state they form a very insipid, though, with strong constitutions, a very wholesome food. They are brought sometimes from Shetland to London with other dried and salt fish.

SUBSECT. 13.—*The Coalfish* (*Gadus Carbonarius*, Linn.).

2120. This is a northern fish, being found in Spitzbergen, Davis's Straits, and the Baltic. It swarms in the Orkneys, where it furnishes a great part of the support of the poor at a certain time of the year; they take it, when under one year old, with rod and line, sitting on the rocks. It is there called the *sillock:* in the second year of its age it comes less frequently to the shore, and is fished from a boat, being named a *cooth:* as it advances in age, it keeps farther out to sea; and, growing to the length of two or three feet or more, it is termed *sethe;* and then it is a very coarse fish. In this state it is split, salted, and dried, for exportation to the Mediterranean. In Edinburgh the young fish are called *podleys*. While under a year old, and till two years, they are a delicate, well-flavoured fish. They can be easily bred in salt-water ponds.

SUBSECT. 14.—*The Mackerel* (*Scomber Scomber*, Linn.).

2121. This is well known to be one of the most elegant in its form among our fish, and the most beautiful in its colours when just taken out of the sea. It was formerly supposed to be migratory, passing the winter in the polar seas, and travelling south every year to deposite its spawn in warmer climates; but the migration of these fish, as well as that of the herring, is now disputed; and most naturalists are of opinion that, during the winter season, it merely retires into the deeper parts of the sea, at a distance from the shores. They appear on our coasts in the spring in immense shoals; but their progress does not correspond with their supposed migration from the north, for they are first met with off the Land's End in March, pursuing a course from west to east, and are found in the bays of Devonshire about April. They are taken off Brighton about April and May, and on the coast of Suffolk about May and June. In the Orkneys, they are not seen till August. This, instead of being any proof of the supposed migration, rather militates against the opinion that they come from the north.

2122. *Mackerel are so prolific* that 540,000 ova have been counted in one roe. Young mackerel, called *shiners*, are caught in August, from four to six inches long; and they are half grown when they retire to the deep water in November. Their principal food is the fry of other fish, and they are voracious feeders. Their ordinary length is from fourteen to sixteen, and even twenty inches, and their weight a pound and a half to two pounds. The largest fish, however, are not considered the best for the table.

2123. *Mackerel is in great request as an article of food;* but it should be perfectly fresh to be in perfection, and no fish spoils more rapidly: in consequence of its being so perishable a commodity, they are allowed to be cried through the streets of London on Sundays. The common idea respecting mackerel is, that they are in best condition when fullest of roe; but at that time this fish, though not impoverished, has but little flavour. It is in the early part of the season, when the roe is not yet full grown, that they have most flavour. There is likewise an after-season, when, in October, they have had time to fatten and to recover after spawning. Full-grown mackerel are occasionally caught on the Cornish coast all through the year. They are taken with large nets; and in some years the quantity caught is enormous. Mackerel is seldom salted in this country, but it appears that in France they are preserved in that manner. The value of this fish was highly recognised by the ancients, who prepared from it a kind of sause, called *garum*, still made at Constantinople, but now superseded through the rest of Europe by the anchovy. A variety of this fish, called the *Spanish mackerel*, is occasionally taken on our coasts, but it is in no estimation.

The *Scad*, or *Horse Mackerel* (*Caranx trachurus*, Linn.) is a coarse fish, which occasionally appears in vast shoals on the British coasts, particularly the southern. It is rarely brought to market, and not esteemed. In Cornwall it is salted and consumed by poor people.

Subsect. 15.—*The Smelt* (*Salmo Eperlanus*, Linn.).

2124. The smelt is a very delicate fish, and much in request. Mr. Yarrell says that the true smelt is almost exclusively confined to the eastern and western coasts of Britain, and that he is not aware of its existence between Dover and the Land's End; what is caught there, and called smelt, being the Atherine or sand-smelt. The smelt ascends rivers and inhabits fresh water from August to May; and, after spawning in March, returns to the sea. It rarely goes far from shore, and is taken in abundance in November, December, and January. It is a very elegant fish: its form is beautifully taper, the skin thin, and the whole body semi-transparent; the scales are small, silvery, and easily rubbed off. It has a peculiar odour, which some compare to that of a cucumber, and others to that of a violet. The Thames used to swarm with this fish; but of late very few have been taken in it. It has been bred in ponds with complete success.

2125. The *Sand-smelt*, or *Atherine* (*Atherina presbyter*, Cuv.), is sometimes sold in Southampton and other parts of the Hampshire coast as the true smelt, to which it is inferior, being more dry; though if dressed with the liver and roe, and without being embowelled, it is excellent. It is plentiful on the south coast of England, where the true smelt is rare.

Subsect. 16.—*The Gurnard* (*Trigla Cuculus*, Linn.).

2126. *The Red Gurnard*, sometimes called the *Cuckoo Gurnard*, is very common on the English and Irish coasts. Its head is remarkably well defended with bony plates and spines, and as they swim near the bottom of the sea, they are extremely tenacious of life when taken in the trawl nets. They are an excellent fish as food, and are in greatest perfection in October, though they are to be had through the winter months.

2127. *The Piper* is a species of gurnard, but more rare on our coast than the last. It is chiefly obtained on the western coasts of Devon and Cornwall, and attains the length of two feet, weighing three pounds and a half. All the gurnards emit some sound when taken from the sea; and the name of this species is given from the noise it is supposed to make. Its flavour is thought by some superior to that of the common gurnard.

2128. *The Gray Gurnard* is not uncommon on our coasts. Its general colour is brownish-gray or greenish-gray, the belly silvery white.

Subsect. 17.—*Conger Eel* (*Muræna Conger*, Linn.).

2129. This large species of eel is found in the European seas, and sometimes, though rarely, in rivers. It is extremely voracious, feeding on other fish, crabs in their soft state, or dead animals of any kind. It grows to the length of from four to ten feet, and some have been taken weighing a hundred pounds. A fishery of congers, at Mount's Bay, in Cornwall, forms a considerable branch of commerce. They are taken in great quantities, and were formerly exported in a dried state to Spain and Portugal, where, being reduced to powder, they were used for enriching soup. At present they are chiefly sold to foreigners as bait for other fish.

2130. *They are not nearly so oily as the smaller eels*, and the fish being white and firm, they are cooked in a great variety of methods. They make excellent soup, are eaten boiled, broiled, fried, and made into pies.

SUBSECT. 18.—*Skate* (*Raia Batis*, Linn.).

2131. *Of all the larger fish of this country, the skate or ray is the most numerous*, and this is owing, in a great measure, to their size. Only the cachalot and shark have a swallow sufficiently large to receive them, and, perhaps, even they are deterred by their defensive armour. In England some have been taken that weighed two hundred weight, and in other seas they have been met with much larger. In deep water they are supposed to be enormous, for it is only the smaller ones that approach the shores. They are very prolific, one female containing sometimes three hundred eggs; but they produce their young alive, and only one at a time, enclosed in a black, square, horny purse, which are frequently found cast upon the shore after the young skate has come out of it. Like other flat fish, they live at the bottom of the sea.

2132. *The skate belongs to the cartilaginous fishes*, that is, those whose bones consist only of firm cartilage. The flesh is thick, white, and extremely nutritive; and, being easy of digestion, forms an excellent food, less esteemed than it deserves to be. It is much improved by crimping, in which state it is almost always sold in London.

From their great abundance, skate is extremely cheap in the fishing towns of England; and as it is the custom there often to cut out only the best part, and throw the rest away, much excellent nutritious food is lost, which in other places would be converted into use. Skate, likewise, admits of being kept fresh longer than any other fish, and, hung up in the sun, it can be dried without salt. In northern countries, great quantities are thus laid up in store. The French consider skate as a very nutritious and excellent fish, and hold it in greater estimation than it is on this side of the Channel. They send their boats to our fishing towns to purchase skate, particularly in Lent, and they preserve it fresh by keeping it covered with wet sand. Skate are taken in abundance all round the coasts of England and Scotland.

There are several species found in our seas besides *Raia batis*, or true skate, as the *long-nosed skate*, the *white skate*, and the *Homelyn ray*, which are of inferior quality, though often crimped and sold for true skate.

2133. *Skate gets in season* in July, and continues so through autumn and the beginning of winter, but is not good in spring or early summer.

2134. *The Thornback differs from the true skate* in having large spines in its back, which are wanting in the latter. It does not grow to the size of the skate, and is considered as rather inferior in quality; in other respects it is very similar. The thornback is taken in greatest abundance during spring and summer, because then they approach nearest the shore for the purpose of spawning; but their flesh is not so firm and fit for the table at this season as in November. The fishermen call the females *Maids*.

SUBSECT. 19.—*Striped Red Mullet* (*Mullus Surmuletus*, Linn.).

2135. The colour of this fish is an elegant rose-red tinged with olive, when on the back, and a silvery coat on the abdomen. They occur frequently on the Cornish coast, and are taken also on the coast of Sussex, but become rare more north. This fish was held in great esteem by the Romans, not only on account of its delicious flavour, but also from its beautiful colour. At present it is a fish in high request, the flesh being white, firm, and of a fine flavour. On our coasts it seldom exceeds fourteen inches in length. Mullets occur sometimes in profusion, and at other times are exceedingly scarce; they are mostly taken with trawl nets, which traverse the bottom of the sea. They appear in the fishmongers' shops nearly throughout the year, but most frequently in May and June, when they are in best condition. Notwithstanding that the usual habitat of this mullet is the sea, it occasionally ascends rivers.

SUBSECT. 20.—*Gray Mullet* (*Mugil Capito*, Cuv.).

2136. The gray mullet, though bearing the same name, is altogether a different fish from the red. It is very plentiful on the sandy coasts of our island, and is observed to assemble in small shoals near the shores in the spring in quest of food, burrowing into the soft mud for worms, and leaving the trace of its head in the form of a round hole. Unlike the salmon, they spawn in the sea; but, like that fish, they ascend rivers for miles. When preparing for these expeditions, they are observed in shoals near the surface of the water, at which time the fishermen endeavour to avail themselves of the opportunity of surrounding them with their nets. The mullet is particularly abundant on the southeast coast of England. It is considered a fine fish; and the spawn is sometimes made into an inferior kind of caviare, by drying and salting it. From its partiality to fresh water, this fish has been thought favourable for the experiment of keeping marine fish in fresh-water ponds; and, accordingly, Mr. Arnold, of Guernsey, has fattened them prodigiously in this manner. Of all the salt-water fishes so introduced into ponds, the gray mullet seemed to be the most improved.

SUBSECT. 21.—*The Herring* (*Clupea Harengus*, Linn.).

2137. This excellent fish is peculiar to the northern seas, and is well known to supply abundance of food, particularly to the poorer classes. The name *herring* is derived from the German *heer*, an army, which expresses the number they appear in. Herrings are met with in great plenty, from the highest latitudes, as low as the northern coast of France. They are also found in vast shoals on the coast of America, as low as Carolina; and they are met with in the Sea of Kamtschatka.

2138. *The herring was supposed to be a migrating fish*, and that its chief rendezvous is the icy sea within the arctic circle, which swarms with insect food in greater abundance than warmer latitudes. Pennant and other authors have described the migration of the herring in a very circumstantial manner, which has been copied into numerous publications.

Notwithstanding the almost universal belief, however, of the migration of the herring from the northern regions to the south of Europe, and the detailed description of it, yet some of the best naturalists of the present day consider these accounts to be in most instances erroneous, and think it most probable that the herring, like the mackerel and the sprat, during the winter months inhabit the deepest parts of the sea, but at no great distance from the shore, or plunge beneath the soft mud at the bottom, from whence they rise in the spring season, and approach the shallower water, in order to deposite their spawn. It is thought that the northern migrations supposed by Pennant and others are impracticable in the short period assigned to them, as the fish, in its swiftest progress, is utterly incapable of moving at a rate so rapid as the term allowed for those migrations would require. Many interesting facts and observations on this subject may be found in Dr. M'Culloch's "Description of the Western Islands of Scotland." That they do move about in wandering shoals, like many other fish, is certain; but what renders it improbable that they come from the polar regions, as has been imagined, is, that they have not been observed there by our navigators. Their movements appear to be extremely capricious; for many of the deep bays of the west of Scotland and Ireland, which they frequent at one time, are entirely deserted in another year without any obvious cause: a circumstance which sometimes proves ruinous to the inhabitants of fishing stations.

2139. *Besides the great quantities of this fish consumed at home in a fresh state, much more is cured with salt and exported.* It has been stated that the Hollanders were the first who began the fishery of herrings on an extensive scale, and observed the several seasons of their passage, about 1163; but it is recorded in the Batavian annals that the Scotch sold their herrings to the inhabitants of the Netherlands as early as the ninth century; and this traffic laid the foundation of a commercial alliance between the two countries which subsisted for many ages. The Yarmouth fishery appears to have had its commencement soon after the landing of Cerdic, the Saxon, in 495, and the inhabitants of the town were long considered as the best curers in Europe. They had an advantage over the Dutch in being nearer to the herring shoals, and in possessing plenty of wood to smoke them, which is extremely scarce in Holland.

Willoughby, in his "History of Fishes," ascribes the art of curing herrings by salt to William Beukelz, a Fleming, who died in 1397; and the term *pickling* is supposed to be derived from him. Yarmouth, however, puts in a prior claim to this art. It is recorded that, in 1220, the Abbot of St. Alban's purchased a large house in Yarmouth, "in order to lay up fish, especially herrings, which were bought by his agents at the proper season for the use of the abbey." Prior to 1238, the inhabitants of the opposite coast of Europe were in the habit of resorting to Yarmouth for a supply of this fish. These and other recorded facts show that the method of preserving herrings, probably by salt, must have been known in England more than 200 years before Beukelz.

2140. *The principal British herring fisheries are on the west and east sides of Scotland and the west of Ireland;* the herrings fished in England are comparatively inconsiderable. Yarmouth and Lowestoffe are the principal places; and very large quantities are also caught at the mouth of the Thames by the fishing smacks of London, Folkestone, Dover, &c., for the London markets, and near the coast of Kent and Sussex for general consumption.

2141. *As food*, fresh herrings, though rather oily, form a very good aliment if used moderately; but that is not the case with pickled and salt herrings; these are only fit for those whose powers of digestion are very strong: in small quantities, with plenty of potatoes or other vegetables, they are less objectionable. Red herrings are used less as food than as a luxury. They excite thirst, and tend to create fever.

For the methods of curing herrings, see Book X., "Preservation of Food."

SUBSECT. 22.—*The Pilchard* (*Clupanodun Pilchardus*, Linn.).

2142. *The pilchard is somewhat allied in general appearance to the herring*, but is thicker, or of a less compressed form, the back more elevated, and the scales much larger in proportion. It is also a smaller fish than the herring, but larger than the anchovy, rarely exceeding the length of eight inches. Its geographical distribution is much more limited than the herring; instead of being found on every part of the British coast, like that fish, it occurs in this country in great numbers only on the shores of Devon and Cornwall. It likewise requires a warmer climate than the herring, abounding in the Mediterranean, and the coasts of Dalmatia, from which Greece and Italy are partly supplied. Pilchards appear usually in vast shoals off the Cornish coasts about the middle of July, and disappear in the beginning of winter, though a few return again after Christmas. Their winter retreat is supposed to be the same as that of the herring, in the deep sea.

2143. *The pilchard fishery is a very productive concern on the coast of Cornwall*, where these fish are cured with salt for exportation. Their appearance on the coast, and their term of remaining, are irregular; but when they come, they often appear in shoals so large and dense as almost to exceed belief. The shoals, either when pursued by enemies, or from other causes, crowd occasionally into bays and harbours in enormous quantities. In 1767 there were taken in St. Ive's Bay 3000 hogsheads of pilchards, each hogshead containing 3500 fish; at another time 10,000 hogsheads were caught at one time.

In Cornwall, besides the great number of persons employed in the fishery, and curing fish with salt for exportation, the poor are fed by them, and a large quantity is generally left, sufficient to supply a valuable manure for the land. The pilchard is a fat, oily fish, more so than the herring, and oil is extracted from them; but the Cornish people, nevertheless, use them as food, and many prefer them to the herring. They make a pilchard pie in the following manner: They clean the white part of some large leeks, scald them in milk and water, and place them in layers in a dish, putting between each layer two or three salted pilchards which have been soaked for some hours the day before; the whole is then covered with a good plain crust: on taking the pie out of the oven, the side crust is lifted up with a knife, and all the liquor being emptied out, its place is supplied with half a pint of scalded cream. Pilchards are not brought to London as such, but the young fry are often sold for anchovies.

SUBSECT. 23.—*The Sprat* (*Clupea Sprattus*, Linn.).

2144. This well-known little oily fish never grows to a larger size than four or five inches in length. It is a wandering fish, visits our shores, and continues with us in large shoals, when the herring and other fish have retired to the deep. They enter the River Thames below bridge about the beginning of November, and leave it in March; and being sold at a low price, are, during their season, a great relief to the poor of the capital. At Gravesend and at Yarmouth they are cured like red herrings. They are sometimes pickled, and, when managed properly, are little inferior in flavour to the anchovy, but the bones will not dissolve like those of the latter. In Cornwall the true sprat is very rare; what has been so called is the young of the pilchard. The coasts of Kent, Essex, and Suffolk are the most productive of them. There from 400 to 500 boats are employed during the winter; and, besides the immense supply to the inhabitants of London, many thousand tons are sold at from sixpence to eightpence per bushel to farmers, who employ them as manure to the land, distributing about forty bushels over an acre; they have even been sent up the Medway to manure the hop grounds in Kent.

SUBSECT. 24.—*White Bait* (*Clupea Alosa*, Linn.).

During the month of July there appears in the River Thames, near Blackwall and Greenwich, innumerable multitudes of small fish, which are known to the Londoners by the name of *white bait*. They are esteemed very delicious when fried with fine flour, and occasion, during the season, a vast resort of persons to the taverns contiguous to the places where they are taken. There were various conjectures about this fish; and though most of them terminated in a supposition that they are the fry of some fish, few agreed to which kind they owe their origin. Some attributed them to the shad, others to the sprat, the smelt, or the bleak. Mr. Donovan, in his "History of British Fishes," states that he had ascertained, past all doubt, that the white bait is the fry of the shad. Mr. Yarrell, however, in his late work on fishes, contests this opinion, and maintains that the white bait is a species distinct from every other fish. It is supposed that the parent fish are not taken, from not coming up high enough in the river. While it was supposed that white bait was the fry of other fish, and that using small nets for taking them was destructive to these fish, such nets were forbidden to be employed; but now that the subject is supposed to be better understood, the fishermen resume the use of these nets without any notice being taken of it, and white bait are commonly sold in London.

SUBSECT. 25.—*The Shad* (*Clupea Alosa*, Linn.).

2145. *The shad* is a sea fish that enters our rivers in May in order to spawn; and this accomplished, it returns to the sea by the end of July. Great numbers are taken opposite the Isle of Dogs in the Thames, but they are in little repute. The usual size is about twelve inches in length.

SUBSECT. 26.—*The Anchovy* (*Clupea Enchrasicolus*, Linn.).

2146. The little fish called anchovy is less used with us as food than as affording an agreeable relish, or for sauces and seasonings. It bears a considerable resemblance to the sprat; and its general length is from three to four inches, or, at the utmost, about four inches and a half. It is found in greatest plenty in the Mediterranean, but also in the Northern and Atlantic seas; and, like the herring, is supposed to leave the deep recesses of the sea, approaching the shores in spring for the purpose of depositing its spawn. The great fishery of anchovies is at Gorgona, a small isle to the west of Leghorn; and they are likewise caught in the Zuyder Zee in Holland, where their fishing is a very profitable branch, and many thousand barrels are annually cured at Amsterdam, Monickendam, &c., for exportation. They are taken in vast quantities, and prepared for sale by salting and pickling; they are put into salt as soon as they are taken, while still alive. The bones dissolve in boiling. The anchovy has been observed (and Mr. Yarrell says more frequently than is usually supposed) on the English coast. It is stated by Mr. Crouch that the anchovy abounds on the Cornish coast towards the end of summer, and that sufficient might be procured to supply Great Britain if attention were directed to the fishery in October and November. Anchovies should be chosen small, fresh pickled, white outside, and red within. Their backs should be round, not flattened. The head, being bitter, is removed in pickling.

2147. The *sardine* is a fish so called in the Mediterranean, flatter in the back and larger than anchovies, and is frequently substituted for them; but it is much inferior to the real anchovy; it is said by some naturalists that the sardine is no other than a small pilchard.

2148. *It is known that many adulterations are practised with anchovies* in England, such as putting anchovy liquor upon pickled sprats or pilchards; and as the red colour is considered essential, red-lead, a poisonous substance, has been employed to colour it; others colour them with cochineal, or red bole. It will be prudent, therefore, to procure anchovies fresh as they come over from Gorgona, and to take care that the flesh itself is red, which is not the case with the sprat. Anchovies are offered for sale in London at the rate of 30*s.* the double barrel, of 38 to 40 lbs., or 16*s.* the single barrel. They will keep long if covered with brine, but soon spoil if exposed to the air.

2149. *Essence of anchovies* is most liable to be adulterated. It may be made in the following manner: Take three pounds of anchovies, pulp them through a fine hair sieve; boil the bones with salt and water, seven ounces of salt to six pints of water; strain, and add seven ounces of flour; then pass the whole through a sieve. This should produce one gallon of the essence. No colouring pigment should be added, though this is directed in most of the receipts; all of them spoil the flavour of the anchovy. The addition of lobsters' eggs will, however, not only be harmless, but will improve the flavour, and, says the "Cook's Oracle," is the only rouge to be recommended.

Subsect. 27.—*The Doru, or John Dory* (*Zeus Faber*, Linn.).

2150. This fish is probably so named from the French *dorée*, gilded, in consequence of its golden-yellow colour. It is a rare fish in general, though sometimes taken in profusion on the Cornish and Devonshire coasts: the average weight is about five pounds; but some specimens sent to the London market have been twice as much. It appears to be a wandering fish, and is in high estimation for the table: the flesh, when dressed, is of a clear white. Most of those purchased in London are brought by land-carriage from Plymouth and other parts of the Devonshire coast. Being a ground fish, they are not the worse for keeping till the second or third day. When fresh caught they are tough.

Subsect. 28.—*The Sturgeon* (*Accipenser Sturio*, Linn.).

2151. This is one of those fishes that migrate from the sea to fresh water: the former serves for its production; but it never goes to any great distance from land, and it is only in large rivers that it grows to its usual size. It is found in the ocean, in the Baltic, the Mediterranean, Black Sea, Caspian, and in prodigious numbers in the large rivers which flow into them. The greatest sturgeon fishery is at the mouth of the Volga, in the Caspian Sea. This fish is likewise abundant in the rivers of North America, and there are regular fisheries in the River Garonne, on the coast of France: occasionally it is taken in the Thames, and is one of those fishes considered as only royal property. The rivers Eske and Eden afford large sturgeon; the form of the fish is lengthened and slender, with a long, projecting snout; its body is defended by hard scales and bony tubercles; the mouth is small, placed beneath, and is without teeth. It is a very strong, vigorous fish, grows frequently to the length of five or six feet, continuing to grow as long as it lives, and has been known to attain the length of twenty feet. Those brought to the London market commonly measure from four to eight feet, and sometimes weigh nearly 300 pounds. Notwithstanding its size, it is said to be of a mild character, feeding on small fish and worms. It is extremely fertile, one fish containing 300,000 eggs.

2152. *It belongs to the class of fishes whose bones are entirely cartilaginous*, and its flesh is much esteemed, being delicate, firm, and white as veal, which, indeed, it resembles so much, that slices of sturgeon, dressed in the manner of veal cutlets, are scarcely to be distinguished from them but by a superadded flavour somewhat like that of the scallop shell-fish. Sturgeon pies are much like meat pies; the flesh is sometimes roasted on a spit, like meat, and is excellent stewed with gravy, and made into soup. Sturgeon is rare in the London market, where it sells for 1*s.*, or 1*s.* 6*d.* per pound. Its season is the winter and spring. As it can seldom be had fresh with us, it is brought pickled from the Baltic and North America: those cured at Pillau are the best.

The sturgeon was in high repute among the Greeks and Romans, and Pliny states that it was brought to table with great pomp, accompanied with music, and ornamented with garlands of flowers.

2153. *Cavaire* is a favourite food of the Russians, prepared from the hard roes of the sturgeon chiefly; the roe is cleaned from the strings and fibres, steeped in strong brine, or salt pickle. It is then dried, and pressed into casks or tubs, and formed into small cakes about an inch thick, and three or four inches in breadth. The red caviare is salted and smoked. The fishery of the sturgeon, for this purpose, is extremely profitable to those engaged in it, and likewise to the government of Russia. Caviare is used by that nation as an article of food in the long Lent of the Greek Church, and on the fast days, which they observe with great strictness: it is exported for the same purpose to Italy and Germany. It also finds its way occasionally to the English table. It has lately been brought nearly fresh to London, in the same state as it is used at Riga and Petersburgh, and may be had at Mr. Ball's Italian warehouse, New Bond-street, at fifteen shillings per cask of three pounds. To be good, caviare should be of a reddish-brown colour, and very dry. It is eaten alone, or with oil and lemon, or vinegar, or with a sauce and pickle, like anchovies. The best caviare, as well as the best isinglass, is made by the Cossacks on the River Ural. In winter the roe is eaten fresh, and it is reckoned that the less salt put with it the better; but without some it will not keep.

2154. *The Sterlet* is a smaller species of sturgeon, seldom exceeding the length of three feet. It is found in the Caspian Sea, and in some of the Russian rivers, and is highly celebrated for the delicacy of its flesh. It is recorded of Prince Potemkin of Russia that, in seasons when the sterlet was unusually scarce, he had been known to have given three hundred rubles for a tureen of sterlet soup. The caviare prepared from the roe of the sterlet is a dainty still more expensive, and is said to be almost exclusively confined to the use of Russian royalty.

Subsect. 29.—*The Tunny* (*Thynnus Vulgaris*, Linn.).

2155. This fish rarely appears upon the English coast; but abounds in the Mediterranean, and is occasionally taken among the western isles of Scotland. It is a large fish, three or four feet in length, and sometimes much more. The flesh is considered very delicious, and something between fish and meat; it is as firm as sturgeon, but finer flavoured. In France it is much used, and dressed in a great variety of ways.

Subsect. 30.—*The Sea Lamprey* (*Petromyzon Marinus*, Linn.).

2156. The lamprey is a singular fish. In its general appearance, it approaches the eel tribe, and is distinguished by seven holes, like shot holes, on each side of the head, which are breathing holes. The generality of British specimens are from twenty to twenty-eight inches in length. This fish is an inhabitant of the ocean, ascending rivers chiefly during the latter part of winter and the early months of spring, and, after a residence of a few months in fresh water, it again returns to the sea. When in motion, it is observed to swim with considerable vigour and rapidity; but it is more commonly seen attached by the mouth to some large stone or other substance, the body hanging at rest, or obeying the motion of the current: so strong is the power of adhesion by this animal, that a stone of the weight of more than twelve pounds may be raised without forcing the fish to forego its hold. Like the eel, it is remarkably tenacious of life: the several parts, when cut in pieces, will long continue to move, and the head will strongly attach itself, for several hours, to a stone, though the greater part of the body be cut away from it.

The lamprey belongs to the class of fishes whose bones, instead of being hard, are mere cartilage; its spine is quite soft, without any protuberances. For many ages it has maintained its credit as an exquisite dainty, and has uniformly made its appearance at the most splendid of our entertainments. The death of King Henry I. is attributed to a too luxuriant indulgence in this his favourite dish. It still continues to be in high esteem, and we are told by Mr. Pennant that the city of Gloucester continues to send yearly, at Christmas, a present of a rich lamprey pie to the king. It is, notwithstanding, by some considered not to be wholesome food. Lampreys are most in season during March, April, and May, and are observed to be much more firm when just arrived from sea than when they have been a considerable time in fresh water. They are found in several of the British rivers, but that which is the most celebrated for them is the Severn. In the mouths of the larger of the European rivers they are sometimes taken in such quantities that it is impossible to use them in their fresh state; they are, therefore, grilled and moderately salted, and afterward barrelled up for sale, with the addition of vinegar and spices, or potted. Lampreys are dressed in several ways; they are boiled, roasted, fried, baked, in pies, or salted and dried for keeping.

2157. *The River Lamprey, or Lampern* (*Petromyzon fluvatilis*, Linn.). This species is smaller than the last, and though found chiefly in the rivers, likewise visits the sea. It is caught in considerable quantities in the Thames, the Severn, and the Dee. It is more plentiful than the greater lamprey.

Subsect. 31.—*The Weaver.*

2158. *The great weaver*, or the *sea cat* of Sussex, generally measures about twelve inches in length, swims near the bottom, and is remarkable for living a long time after it is taken out of the water. It is also armed with very sharp spines, which inflict wounds difficult to heal, except friction with oil be used. The fishermen, consequently, cut off these spines previous to bringing them to market. They are a sort of marine perch, and are excellent.

2159. *The lesser weaver* is more common on our coasts than the great weaver, and, having the faculty of striking with its sharp spines, is often called the *sting fish.*

SUBSECT. 32.—*The Wolf Fish, or Sea Cat* (*Annarrhichas Lupus*, Linn.).

2160. This is almost exclusively a northern fish, taken in the north of Europe, the Orkneys, and the coasts of Yorkshire and Norfolk. It has a ferocious-looking head, resembling a cat, and is furnished with strong teeth, with which it inflicts severe wounds. It does much mischief to the fishermen's nets. Those who have eaten it describe it as delicious; but few can overcome the prejudice excited by its appearance. The skin is very thick and strong, and is converted by the northern people into very durable bags.

SUBSECT. 33.—*The Bass.*

2161. *The bass* is a marine perch, found along the whole line of the southern coast of England, and in the Bristol and St. George's Channels; also occasionally on the coast of Scotland. The ordinary size of this fish is from twelve to eighteen inches in length, though it sometimes attains fifteen pounds in weight. They feed upon small fish and crustaceæ, and are caught by angling as well as the net. On the Kentish coast they are known by the name of *sea-dace.* They generally spawn near the mouths of rivers, and live very well in Mr. Arnold's fresh-water lake in Guernsey. They are fish of a good flavour, although by some reckoned coarse

SUBSECT. 34.—*The Sea Bream* (*Pagellus Centradontus*, Cuv.).

2162. This is not an uncommon fish on the south coast of England, and may be frequently seen during the summer in the fish-market of Hastings: they are abundant in Cornwall. The young are commonly known by the name of *chads*, and it is said that the fish spawns twice in the year. It is not much in esteem for the table. Mr. Yarrell recommends the following as the best mode of dressing the sea bream: "When thoroughly cleaned, the fish should be wiped dry, but none of the scales should be taken off. In this state it should be broiled, turning it often, and if the skin cracks, flour it a little to keep the outer case entire. When on table, the whole skin and scales turn off without difficulty, and the muscle beneath, saturated in its own natural juices, which the outside covering has retained, will be of good flavour."

SUBSECT. 35.—*The Lump Sucker* (*Cyclopterus Lumpus*, Linn.).

2163. This fish is sometimes seen at the fishmongers', hung up as a curiosity. It is eatable, but has no particular good quality.

SUBSECT. 36.—*Dog Fish* (*Squalus Canicular, S. Catulus*, Linn.).

2164. These fish belong to the shark tribe, and several species abound on our coasts, where they are very destructive to the fish, being extremely voracious. They are taken frequently in the nets with other fish, but are seldom used as food, being very full of oil, and strong tasted; nevertheless, in the northern parts of the kingdom, as in the Orkney and Shetland Islands, they are dried in the smoke, and even looked upon as dainties by the poorer sort of inhabitants.

SUBSECT. 37.—*The Whale.*

2165. The whale being the largest of all animals, we might suppose that its flesh is too coarse for food; that, however, is not the case. This animal, being one of the *mammalia*, suckling its young with milk, and breathing air without separating it from the water by means of gills, is not properly a fish, and its flesh is much like beef. Parts of the animal, particularly about the tail, are said not to be contemptible as food even by those who are not pressed by hunger; and some species, as the spermaceti whale, are very generally consumed by the Greenlanders, and other inhabitants of the arctic regions.

SUBSECT. 38.—*The Porpoise.*

2166. The porpoise was once a favourite at the tables of the great in this country, and was eaten with a sauce composed of vinegar, bread-crumb, and sugar. The flesh of the young has been compared to veal; but at present, instead of its being "food for kings," not a beggar will touch it.

SUBSECT. 39.—*The Dolphin.*

2167. The dolphin, though celebrated by the poets for its gambols, does not appear to be at present as much valued as formerly, when we read of an English feast consisting of a "roasted dolphin with proper sauce."

SECT. III.—FRESH-WATER FISH.

SUBSECT. 1.—*The Salmon* (*Salmo Salar*, Linn.).

2168. The salmon is styled by Walton, the celebrated angler, "*king of fresh-water fish.*" It is to be found all over the north of Europe and Asia, from Britain to Kamtschatka, but never ventures into the warm latitudes: it has been met with on the coasts of Greenland, and has been seen in some of the rivers of France, but none have been caught so far south as the Mediterranean.

2169. *It is a migratory fish*, and annually ascends rivers in large shoals for the purpose of spawning; but it is only to be found in such rivers as communicate with the sea, in consequence of which it is by some considered as a sea fish. The Romans were well acquainted with it, and our English name is borrowed from their salmo. The long migration of the salmon just before the spawning season forms an interesting part of their history.

It is certain they receive the principal part of their food in the sea, but it appears that the ova or eggs can only be hatched, and the young fish live, in fresh water; in the early period of a salmon's existence, salt water being fatal to it: also, that the causes of the alternate migrations of salmon are the impulse of propagation, and the search after food. In their debilitated condition after spawning, when they are "out of season," they betake themselves to the deep sea in which their haunts are not known.

Having recovered their vigour, they crowd in shoals towards the coast, and roam about in the estuaries until the autumnal floods entice them to enter the rivers. While thus detained on the coast and in the estuaries, they are pursued and preyed upon by numerous herds of seals and grampuses, which consume many more than fall to the lot of the fishermen. The early run fish are in good condition, the roe being still small, and they then mount towards the higher and more distant branches of the river.

In ascending the rivers they not only make their way against the most rapid currents, but overcome obstacles that might be supposed insurmountable. When they arrive at a waterfall or a weir, they leap out of the water to get over it. The salmon leap at Leixlip, on the Liffey, is thirty feet high. When there is little water in rivers they cannot ascend, and are obliged to take advantage of freshets. Towards August and September the roe has acquired such a size as to render the fish nearly useless as food, and greatly to limit the extent of its migrations.

Having arrived at a suitable spawning-ground, for which they prefer a gravelly bottom, the salmon pair, and proceed to the shallow pebbly fords at the top and bottom of pools, and then, in company, make their spawning bed, which sometimes reaches from twelve feet in length to ten in breadth. This bed is furrowed by the parent fish working up against the stream, and the spawn is deposited and covered at the same time. This process frequently occupies more than a week, during which the eggs deposited by a single fish sometimes amount to the astonishing number of 20,000! This spawning season extends from the end of October to the beginning of February, and occurs nearly about the same time throughout all the rivers of the United Kingdom; and during this period salmon is wholly unfit for food.

The parent fish, having thus accomplished the important purposes of their migration into the river, now retire into the deepest pools, were, after remaining a considerable time, they direct their course towards the sea, chiefly during the months of February, March, and April, the male fish appearing to migrate earlier than the females.

The eggs of the salmon remain in the gravel for several months, exposed to the influence of running water; and in the course of the month of March the fry are hatched. At first they are less than an inch in length; but upon leaving the spawning bed they betake themselves to the neighbouring pools, where they speedily increase to two or three inches. They then appear in incredible numbers, and descend to the sea in April, May, and June. It is said that, on first meeting with the tide, they remain some days in the brackish water till they get inured to the change.

At different periods of their progress the young fry have received different names, and there have been doubts whether they all belong to the salmon or to other fish. When under two pounds' weight they are called by some London fishmongers *salmon peel;* and when larger, but under a year old, they are termed *grilse.* These fish of the year breed during the first winter, and return from the sea next spring with the roe enlarged, as has been described, for the purpose of spawning, accompanied generally by the parent fish, when the season of fishing commences, and they are considered to be best as food prior to their entering the fresh water.

Thus the salmon passes the summer in the sea or near the mouth of an estuary; in autumn they push up rivers; in winter they inhabit the pure fresh water; and in spring descend again to the sea. From their regular change every year from salt water, it might be supposed that they could not be bred and kept altogether in a fresh-water lake. The experiment has, however, been tried with success, but it is said that the fish is inferior in flavour to those which have access to the sea.

2170. *When the salmon is in the sea, and about to enter the rivers for the purpose of spawning, or shortly after entering the rivers, it is in the highest perfection;* the flesh is firm and of a fine red colour, and the flavour excellent. The sides are of a bright silvery hue, with few dark spots: great numbers are caught at that time.

When the fish has spawned and is returning to the sea they have fallen off in condition; the colour has become dull, and the sides are streaked all over with red and dark spots; the rays of their skin are jagged and torn, part of their scales are torn off, and their gills are sometimes infested with parasitical fresh-water worms, which stick to them, and which they get rid of in the sea. At this time they are not wholesome, and are supposed to be productive of disease. This circumstance, however, is not sufficient to prevent those who have an opportunity from catching and eating the fish in that state: and the legislature has found it necessary to fix the periods at which salmon fishing is lawful. When they first arrive at the rivers from the sea, an insect, called the salt-water louse, is found adhering to their sides, and is a proof that the fish is in season. Although this subject has excited so much interest, and been so carefully studied, yet so difficult is it to acquire an accurate knowledge of fish, that the habits of the salmon are still involved in some obscurity. It has been said that every salmon, when wishing to return to fresh water after having been in the sea, goes up the same river in which he was spawned, and that each river has its own fish; but this is improbable: perhaps each fish may prefer his own river, but that he can find it always is unlikely.

The salmon is a voracious feeder, and its food consists of small fishes and marine nisects. It increases rapidly in size while in the sea, where it finds the greatest abundance of food.

It is thought that the breed of salmon is decreasing in Britain, from the amazing number that are killed in ascending to spawn, and from the want of protection of the fisheries.

2171. *The chief salmon fisheries in Europe* are along the coasts of England, Scotland, Ireland, and the Baltic. The fish is generally taken by nets, and also in the rivers, by a kind of locks called *weirs*. Near Whitehaven they are also speared. As they are caught in rivers and estuaries, the salmon fisheries are chiefly private property. The consumption of this fish in the metropolis is immense, and the London market is supplied principally from the rivers of the northern part of the island. Formerly salmon was caught in the Thames in abundance, and this was reckoned the finest; but since the water has been deteriorated by numerous sewers and gas works, this fish no longer frequents the river. The salmon of the Severn and Wye is excellent, and is first in season of any in England. Formerly such part of the salmon of the North as could not be consumed at home was pickled and kitted after being boiled, and was in this state sent up to London, under the name of Newcastle salmon. Within the memory of many now living, salted salmon formed a material article of household economy in all the farmhouses in the vale of the Tweed; insomuch that in-door servants used to stipulate that they should not be obliged to take more than two weekly meals of salmon. Its ordinary price was then 2*s*. a stone of 19 lbs. At present an immense quantity is taken in the Tweed, and is sent to London by the Berwick smacks. The fishing in the Tweed begins on November 30th, but there are few taken till after Christmas; and it ends at Michaelmas. Salmon, like all fish that swim near the surface of the water, cannot be eaten too fresh; its fine flavour diminishes rapidly after capture.

2172. *About the year* 1788 *the method was first resorted to, now so much practised, of packing salmon in ice to preserve it*, which enables the proprietors of the fisheries at a distance to send it to London in a fresh state; and salmon preserved in this manner is now despatched in fast-sailing vessels from the Spey, the Tay, the Tweed, the Dee, and other rivers of Scotland. This has amazingly altered the price of the fish, and increased the value of the fisheries. Icehouses are now built at the several rivers, to keep the fish in until the time for sending it arrives. A great deal of fish is often spoiled by this mode, and the flavour is materially injured by freezing. There are also salmon fisheries in some of the English and Irish rivers, but inferior to those of Scotland. The price of salmon in the season in London is frequently as low as 9*d*., and even 6*d*., per lb.

2173. *Salmon is cured or preserved* in various ways: salted or pickled, and dried. For the method of pickling salmon, see Book X., "Preservation of Food."

2174. *As food*, salmon, when in high perfection, is one of the most nutritive and delicious of our fish; but as it is very oily it is rather heating, and with some persons not very digestible; with most constitutions it requires the addition of condiments, as Cayenne pepper and vinegar. It is thought by some that the addition of shrimp, lobster, and other rich sauces, with which it is usually eaten, increases its indigestibility; but there does not appear to be any distinct knowledge on this subject, so much depending upon peculiarity of constitution. It requires to be very well boiled, otherwise it is unwholesome; and when in the best condition and season, it has a fine curdy matter between the flakes, which is a proof of its perfection, and the flavour is then very much superior; but this is seldom seen except near to the places where it is caught, as it melts away in keeping.

2175. *When the salmon runs from six to ten pounds* they are very good fish, and make handsome dishes sent to table whole; but by a late act of Parliament no salmon is permitted to be sold by the fishmonger of less than 6 lbs. weight, to prevent the destruction of the breed.

2176. *We find the following account of the perfect mode of cooking the fish* in Sir Humphrey Davy's "Salmonia:" "We must now prepare him for the pot. Give him a stunning blow on the head to deprive him of sensation, and then give him a transverse cut just below the gills, and crimp him by cutting to the bone on each side, so as almost to divide him into slices; and now hold him by the tail that he may bleed. There is a small spring, I see, close under that bank, which, I dare say, has the mean temperature of the atmosphere in this climate, and is much under 50°; place him there, and let him remain for ten minutes, and then carry him to the pot, and let the water and salt boil furiously before you put in a slice, and give time to the water to recover its heat before you throw in another, and so with the whole fish, and leave the head out, and throw in the thickest pieces first."

The rationale of this process of crimping is thus given: "I conclude that the fat of salmon between the flakes is mixed with much albumen and gelatin, and is extremely liable to decompose, and by keeping it cool the decomposition is retarded, and by the boiling salt and water, which is of a higher temperature than that of common boiling water, the albumen is coagulated, and the curdiness preserved. The crimping, by preventing the irritability of the fibre from being gradually exhausted, seems to preserve it so hard and crisp, that it breaks under the teeth; and a fresh fish not crimped is generally trout."

Salmon crimped in this manner, which preserves the natural taste, should have no other sauce than a spoonful of the salt and water in which it has been boiled, with the addition of a little lemon juice (or, if that cannot be had, vinegar) and pepper. Some persons, however, object to the curdy state of the fish, and prefer it when it has been kept for a day or two, when the curd has partly softened into oil, which gives a richer taste.

2177. *Salmon is seldom taken by the angler in the south part of Britain*; but in Scotland, as well as in Ireland and Wales, fishing it by the line is much practised, and affords much amusement.

SUBSECT. 2.—*The Salmon Trout* (*Salmo Trutta*, Linn.).

2178. This, called also the *sea trout*, appears to connect the salmon and the trout. It, like the salmon, frequents both the sea and rivers, ascending the latter to spawn. It is chiefly found in the rivers of mountainous countries, and is frequent in Wales and the lake district of England. It seldom exceeds a foot in length, but is a very delicious fish.

SUBSECT. 3.—*The Bull Trout* (*Salmo Eriox*, Linn.).

2179. This fish is not held in such estimation as the salmon or salmon trout, but sometimes attains the weight of fifteen or even twenty pounds. Few are sent to the London market.

SUBSECT. 4.—*The Common Trout* (*Salmo Fario*, Linn.).

2180. This fish is an inhabitant of clear and cold streams and lakes in most parts of Europe, and is less rich and oily than the salmon, but is esteemed a great delicacy for the table. It is supposed that there are several varieties; the colour of the flesh of some being reddish, of others yellowish, and of some it is white; the first are generally preferred. The female is of a brighter colour, and more beautiful than the male. It swims rapidly, often, like the salmon, leaping to a great height in ascending the rivers. They are in season during the summer months, or from the end of February till August, but are best in May and June, and afford great sport to the angler. They are of more quick growth than any fish except the salmon, but do not live to a great age; the duration of its life is supposed not to exceed eight or ten years. Its general length, when full grown, is about twelve or fifteen inches. When trout are in season, the scales are very bright and silvery; they should be cleaned and gutted when they are to be sent to any place, and closely packed, lying on their backs in a willow basket with dry straw; grass or rushes are apt to heat and spoil the fish. Before being dressed, they are much improved by crimping, and epicures direct that they should be killed by a blow on the head the moment they are taken out of the water. When the trout have arrived at home, lay them on cold stones until wanted; they should be dressed the day they are caught, and never put to soak or soften over the fire in cold water, as is the general practice. If trout are suffered to remain in water after being sufficiently boiled, they will directly become soft, and lose all the firmness given them by crimping. They should be boiled in water with a handful of salt put in. Salt water acquires more heat than fresh, and, consequently, hardens the curdy matter of the fish more. Trout feed well in stews, and will attain the weight of a dozen or fifteen pounds.

SUBSECT. 5.—*Samlet.*

2181. A fish, called the *parr* or *samlet*, about five inches in length, appears in our rivers in autumn, and has been supposed by some to be a distinct species; but it has been made out by Mr. Shaw that it is nothing more nor less than the fry of the salmon.

SUBSECT. 6.—*Charr* (*Salmo Alpinus*, Linn.).

2182. This delicious little fish, which is considered as superior to the salmon, inhabits deep lakes in alpine countries, even those which are extremely cold, and covered with ice half the year. Its flesh is rich, extremely red, and full of curd or fat. A few are found in certain lakes in Wales; but the largest and most beautiful are in the Lake of Windermere in Westmoreland: these are nine or ten inches in length. Being considered as a rarity, this fish is often preserved potted. Its figure is rather more slender than that of the trout. There are several varieties; that of Wales is different from the charr of the lakes of Westmoreland.

SUBSECT. 7.—*The Grayling* (*Salmo Thymallus*, Linn.).

2183. This fish is not met with in the rivers near London, and seldom in the south of England; but, being an alpine fish, delighting in rivers with rocky bottoms, it abounds in the rivers of Derbyshire, Wales, the Severn, Wye, and Trent. In shape it resembles the trout, but it is rather longer and more slender, being generally about sixteen inches in length. It is much esteemed as a table fish for the delicacy of its flesh, which is firm, white, and of a fine flavour. It is considered in the highest season in the depth of winter. When first taken out of the water, it has a very peculiar smell, resembling thyme, said to be occasioned by its feeding upon water thyme. As the trout is a spring and summer fish, the grayling may be considered an autumnal and winter fish. It has been supposed to be migratory, but Sir H. Davy has shown that it cannot bear even brackish water.

SUBSECT. 8.—*The Gwinead* (*Salmo Lavaretus*, Linn.).

2184. This is said to constitute an intermediate tribe between the trout and the herring; and, like the latter, it dies the instant it is taken out of the water. It has been called the fresh-water herring. Like the charr, it is an inhabitant of lakes in high mountainous regions, and in summer approaches the shores in vast shoals in search of food. It abounds in the lakes of Wales and Westmoreland, and is taken by nets. It is nearly a foot in length, but is considered as an insipid fish. The poorer classes salt them.

Subsect. 9.—*The Pike* (*Esox Lucius*, Linn.).

2185. The pike is styled by Walton the "tyrant of the fresh waters," as the salmon is "the king." It is found abundantly in most of the European lakes, particularly in the northern parts; and although it has been disputed whether it is indigenous in England, yet it is the opinion of our best naturalists that there is sufficient proof of its being a native. Its usual colour is a pale olive gray, deepest on the back, and marked on the sides by several yellowish spots or patches; the abdomen white, slightly spotted with black; and its mouth is furnished with a prodigious number of teeth. The size of the English pike is considerable. Instances have been known of their weighing forty pounds, measuring three feet in length; but in Lapland and Russia they attain the size of eight feet. The pike is highly prolific, and their multiplication is immense in the northern parts of Russia and Siberia, where they are taken in the greatest plenty, and constitute an article of commerce, being prepared by salting and drying for exportation.

The voracity of this fish is notorious. It subsists on other fish, but will also devour frogs, rats, serpents, and other reptiles, and even the young of aquatic fowl. It is also related that it will sometimes bite the noses of cattle who come to drink, as well as the hands of persons who put them into the water where it is kept; but stories respecting its voracity have been exaggerated. It is a remarkable, as well as a fortunate, circumstance, that in the summer months, when the fry of other fish are so numerous, the digestive functions of this fish are rather in a torpid state, by which its voracity is diminished. It is very long-lived: Pennant mentions one ninety years old. They are occasionally kept in ponds, but are expensive to maintain, as they require much food, and are destructive to other fish.

The flesh is of a good quality, but it is a dry fish; and when it makes a good dish, it is much indebted to stuffing and sauce. If small, they will do fried; but if large, they are best roasted. The pike of the Medway, which feed chiefly on smelts, are of excellent flavour, and that of Hornsea Weir, in Norfolk, is much esteemed. In the time of Edward I. this fish was scarce in England, and was only introduced at great feasts, its price being higher than that of salmon, and ten times that of turbot.

The terms of *pike* and *jack* refer only to the age of the fish, the latter name being employed where it has not attained more than three pounds in weight, or more than twenty-four inches in length. It is stated by Sir John Sinclair as a fact which ought to be better known, that it is dangerous to swallow the bones of this fish, as they are sharp, and of a texture so peculiarly hard that they will not dissolve in the stomach.

Subsect. 10.—*The Carp* (*Cyprinus Carpio*, Linn.).

2186. The carp is found in rivers and ponds; but they appear to prefer slow and stagnant waters. Their usual length in this country is from twelve to eighteen inches, but in warmer climates they often attain the length of two or three feet, and weigh from twenty to thirty pounds. In the Lake of Como they are said even to weigh occasionally 200 lbs. The usual food of the carp consists of worms and aquatic insects; but they feed also on herbs, and, when in course of fattening for the table, bread and milk. It is extremely prolific, and very tenacious of life. As they live long after being out of the water, it is recommended to kill them as soon as they are taken, otherwise they waste.

Carp are easy of digestion, and afford pretty good food, but are greatly indebted to the cook for the estimation in which they are held. They are frequently kept in fish ponds, and live to a great age; some live even a century or more: they may be tamed so as to feed out of the hand.

The sale of carp constitutes a part of the revenue of the nobility and gentry in Prussia, Pomerania, Saxony, and other places in Germany; consequently, in these countries, the cultivation of carp is regarded with particular attention. The southern parts of Europe are most congenial to it; a few breed in the ponds in Scotland; it is supposed to have been first introduced into England in 1514. Its season is the spring, in March and April, and from that till October they are to be had; in winter they are supposed to lie in the mud.

A variety, called the *Grecian carp*, is found in some of the ponds about London, in the vicinity of the Thames, and is also common in several of the counties of England. Their usual size is half a pound; and they are supposed to have been introduced from Germany.

2187. *The gold carp*, or *gold fish* (*Cyprinus auratus*, Linn.), is one of the most beautiful and interesting of all the finny animals, but better known among us for its value as an ornament than for its qualities as food, although they are sufficiently large and numerous in some places, as in the Mauritius, to be served up at table as fresh-water fish. The extreme elegance of their form, the splendour of their scaly covering, the grace and agility of their movements, and the facility with which they can be kept alive in small glass vessels, cause them to be ranked among the most pleasing of our pets. This fish breeds freely in small ponds, and even in tanks, in this country; but particularly so, if by any contrivance the temperature of the water can be kept a few degrees above the ordinary mean.

Subsect. 11.—*The Perch* (*Perca Fluviatilis*, Linn.).

2188. This is one of the most common, and, at the same time, one of the best of our fresh-water fishes; its colours are likewise brilliant and striking. It is found in almost all the lakes and rivers in Britain and Ireland, and likewise through the whole of the temperate parts of Europe. It is remarkably voracious, feeding upon worms, insects, and small fish, and is very prolific; a perch weighing half a pound will contain 280,000 ova. The spawning season is at the end of April or beginning of May; and perch angling commences in February, continuing till the cold weather, if winter comes on. The perch is one of our largest fresh-water fish; one weighing a pound is a good fish, and one of three pounds weight is reckoned very large; but they have been known to reach even eight or nine pounds. They abound most in deep, dark, sluggish rivers, and delight to lie about bridges, mill pools, and in any deep and dark holes in the still parts of water, or the gentle eddies about flood-gates, and similar places. Its flesh is white, firm, of a good flavour, and easy of digestion. It is covered with thick scales, which are troublesome to remove; and is so tenacious of life, that they may be carried sixty miles in straw, and yet survive the journey. They are best crimped the moment they are taken out of the water.

2189. *The Ruffe*, or *Pope* (*Perca cernua*, Linn.), is a small fresh-water fish, closely allied to the perch, and found commonly in all the rivers and canals of England, preferring slow, shaded streams; they abound in the Thames, Isis, and Cam. It is much like the perch in flavour, being firm, delicate, and well-tasted, and is excellent broiled in buttered paper.

SUBSECT. 12.—*The Roach* (*Cyprinus Rutilus*, Linn.).

2190. This fish inhabits deep, still rivers with a sandy bottom, in Europe and the adjacent parts of Asia; and is very numerous in most rivers of England. It seldom exceeds a pound and a half. It spawns in May, and is in season from September till March; it is very fertile, the eggs are greenish, but become red by boiling. The roach is a yellowish, silvery fish of the carp kind, and will breed in ponds, but not so well as in rivers. Some prefer dressing them by scoring across the sides, and broiling them with the scales on. It is rather an insipid fish, and very bony. The finest are caught in the Thames about the middle of May, or early in June, or afterward in October; vast shoals are taken in Loch Lomond with nets. "As sound as a roach" is a proverb; but this is derived from the French name of this fish being *roche*, which also signifies a rock.

SUBSECT. 13.—*The Fresh-water Bream* (*Cyprinus Brama*, Linn.).

2191. The bream is found in shoals in rivers and lakes, particularly when the latter are large, as those of Cumberland. It also occurs in most of the rivers near London, and is found in abundance in the River Mole, and some in the Regent's Canal. It may also be bred in ponds. It feeds upon worms and some vegetables, and much resembles the carp. Its best season is May; some think in September. It is not much esteemed for the table, being insipid and very bony. It sometimes grows to the length of two feet, weighing ten pounds.

SUBSECT. 14.—*The Tench* (*Cyprinus Tinca*, Linn.).

2192. The tench is fine-flavoured, and generally considered as a rich fish in England: it appears to be a native of most parts of the globe, inhabiting chiefly large stagnant waters with a muddy bottom, as well as rivers. Its general length is about twelve or fourteen inches, but it grows sometimes to two or three feet; seldom weighing five pounds. Like the common carp, tench delight in warmth; they are scarce near London, and thrive best in foul and weedy waters. Some extensive tracts of stagnant water in Norfolk abound in tench, from which they are removed to stews, where they are fattened upon a mixture of greaves and meal. They do not thrive northward, and few are found near Edinburgh. From the facility with which they may be bred, and the ease in transporting them, from their tenacity of life, they perhaps deserve more attention than is paid to their cultivation. They spawn in the spring.

SUBSECT. 15.—*The Gudgeon* (*Cyprinus Gobio*, Linn.).

2193. This fish is of the carp genus, and in length about eight or nine inches at the utmost, seldom weighing more than half a pound. It is found in gentle streams and lakes. It is tenacious of life, and remarkably fertile. Gudgeons are in season in the spring, or from March and April to May, and may be had for five or six months; yet in the hot summer they are very indifferent. They are firm, well-flavoured fish, and much esteemed for the table, being little inferior to the smelt. They should be cooked in a frying-pan, in a few hours, or as soon as possible, after they are caught, and without being scaled or opened; they only require wiping with a wet cloth: opening and washing spoils them. They afford much amusement to anglers, fifty dozen a day having been taken. Being a gregarious fish, they may be seen in summer in the bottoms of clear rivers by hundreds together, and they will live and breed in ponds. They are very fine and numerous in the Rivers Thames, Lea, Mersy, Colne, Kennet, Avon, and also in the New River. The London fishmongers keep them alive for several weeks in leaden or stone tanks, constantly supplied with fresh water. In Bath, they are exposed for sale alive in tubs, and are thus to be had in perfection: they are considered as very easy of digestion, and therefore fit for invalids. Of the genus Cyprinus, some are migratory, inhabiting both the fresh and salt waters, while others remain in fresh water throughout the year.

Subsect. 16.—*The Barbel* (*Cyprinus Barbus*, Linn.).

2194. *This is a common fresh-water fish*, belonging to the carp family, which derives the appellation of *barbus*, bearded, from the upper jaw advancing far below the lower, and in having four appendant barbs at its mouth. It is found during summer in the rapid currents, and at the stony bottoms of tide rivers, retiring at the approach of winter to the more still and deeper places. Barbels sometimes grow to the length of two or three feet. They are ground, or bottom fishes, lurking among the stones and under-banks, and are usually found when moderate floods bring down small animals, as snails, leeches, &c., as food. There is an ancient idea that the flesh of the barbel is unwholesome, which is, perhaps, a prejudice; but it is not of a very good flavour, and is little esteemed: no doubt when the fish are out of season they are, like most other fish in the same condition, not wholesome. They are seldom eaten except by the lowest of the Jews. They are understood to be very voracious and indiscriminate in their feeding; and it is said that the roe is sometimes violently cathartic. The Thames, from Putney upward, produces barbels of large size and in great quantities; also the Lea in Essex; but they are chiefly valued as affording sport to the angler.

Subsect. 17.—*The Dace* (*Cyprinus Leuciscus*, Linn.).

2195. This fish is of the carp genus, and has a bright, silvery colour. It is considered to be light, nutritious food, though full of bones, and is caught in most rivers and streams, but does not thrive in ponds or still waters. These fish never attain a great size, seldom weighing a pound. They are cooked in the same manner as roach, which they much resemble, and to which they are rather superior, though not so plentiful. They are gregarious, swimming in shoals, and spawning in June. The *Graining* is a variety of the dace, rather more slender.

Subsect. 18.—*The Rudd* (*Cyprinus Erythropthalmus*, Linn.).

2196. This fish is very common in the Thames and other rivers of England, as well as the rivers of the Continent. It may be often purchased in Hungerford fish-market, but is sometimes mistaken for roach, to which it is inferior, the flesh being soft and full of bones. It seldom attains two pounds' weight. The roach, bream, and rudd are much alike.

Subsect. 19.—*The Chub* (*Cyprinus Cephalus*, Linn.).

2197. This is a river fish, of the carp genus, somewhat resembling the tench. They are very common in England and Scotland, and delight in deep holes in ponds and canals, but chiefly in clear and rapid rivers. When full-grown, they are from twelve to fifteen inches long, and in weight four or five pounds. When quite in season, and only two or three pounds, they greatly resemble carp, and are usually dressed in the same manner; but they are not very palatable, being watery, tasteless, and bony, and are apt to acquire a yellow colour in boiling; they are therefore held in little esteem. The best manner of dressing this fish is to stuff and roast, or broil it with the scales on, when it is pretty good. It affords good amusement to anglers on the Thames.

Subsect. 20.—*Bull's Head, or Miller's Thumb.*

2198. This singularly-formed fish is of the gudgeon kind, with the scales extremely small, the head large and flat, and the mouth wide. It seldom exceeds five or six inches in length, and is met with in almost all shallow rivers, abounding in the New River. The fish is well tasted, and turns red or salmon colour on boiling.

Subsect. 21.—*Loach* (*Gobitis Barbatula*).

2199. The loach is a very small fish, generally about three inches long, having a round body with six wattles, or barbs, at its mouth. It is not very common, but is found in small brooks and rivulets. It is chiefly used as bait for fishing large eels and perch; but is delicious fried in batter, or with eggs and crumbs of bread.

Subsect. 22.—*The Bleak* (*Cyprinus Alburnus*, Linn.).

2200. This is of the carp genus, and is abundant in most of our rivers, particularly the Thames and Lea. It is in little esteem for the table, being chiefly taken for the sake of its beautiful, silvery scales, which are made use of in the manufacture of artificial pearl; but it is also occasionally substituted for the anchovy, though it has not the same flavour. Its length is about five or six inches, slender in shape, colour bright silvery, with the back olive-green. Its tail is forked, and, from its continual motion, it has been called the river swallow; by some the fresh-water sprat.

2201. *Stickleback.*—This very small fish, which is generally under two inches in length, is a frequent inhabitant of rivers, ponds, and marshes, as well as the sea; it receives its name from the sharp spines on its back. It is sometimes very troublesome in fishponds when it gets into them, being extremely pugnacious, and attacking the larger fish. In the fens of Lincolnshire they are in such quantities as to be taken out in cart loads, and are employed to manure the fields.

Subsect. 23.—*The common Eel* (*Murœna Anguilla*, Linn.).

2202. This fish is migratory, and inhabits both salt and fresh water; it is, accordingly, taken in rivers, lakes, and ponds, as also in the sea. In its form it makes a near approach to the reptiles, having no fins except the pectoral. In the water, no fish is more vivacious, and, as it clings to life very tenaciously when out of the water, it may be kept alive for several days in wet sand. It is, however, very sensible of cold, and, to avoid this, it buries itself under the mud in the winter. There are no eels in the arctic regions, and none in Siberia.

In some parts of Europe the eel fishery is of surprising magnitude. Dr. Black says that in some places near the mouth of the Baltic so great a quantity is taken that they are salted for exportation, and conveyed by wagons into Saxony, Silesia, &c. Two thousand have been taken in Jutland by a single sweep of the net, and in the River Garonne sixty thousand have been caught in a day by a single net. Ponds are sometimes appropriated in England to the raising of eels; and large quantities are caught in the Thames and other British rivers.

2203. *The consumption of eels in our large cities is considerable.* The London market is principally supplied from Holland, by Dutch fishermen. Mr. Yarrell observes, "There are two companies in Holland, having five vessels each; their vessels are built with a capacious well, in which large quantities of eels are preserved alive till wanted." One or more of these vessels may be constantly seen lying off Billingsgate; the others go to Holland for fresh supplies, each bringing a cargo of 15,000 to 20,000 pounds weight of live eels, for which the Dutch merchant pays a duty of 13*l.* per cargo for his permission to sell.

2204. *As an article of food*, eels are extremely rich and nutritious; but on account of the large quantity of oil which they contain, they are apt to occasion derangements of the digestive function, and require as a corrective to be eaten with vinegar, or some other condiment. Their use in pies is well known. They are also eaten fried, stewed, and plain boiled.

2205. *There are several varieties of the fresh-water eel.* The true *silver eel*, so called from the bright colour of its belly, is caught in the Thames, and is superior to most others. Those taken in running water are preferable to what are taken in ponds; the latter often have a rank, muddy flavour. The *Dutch eels* sold at Billingsgate are of this kind. The *sand eel* is a small fish of a delicate flavour, found buried six or eight inches in the sand left dry at low water.

2206. The body of the eel is covered with a slimy mucous substance, which makes them very slippery, and difficult to hold in the hand, whence the well-known saying. It is a common notion that eels have no scales; but that is an error; they have scales, which are easily seen when they are wiped and dried, particularly if a magnifying glass be used.

2207. *The cruelty of skinning eels alive may be avoided* by first cutting off the head, which destroys the sensibility. The writhing motions which they then exhibit in being skinned are thought not to be owing to their being sensible of pain, but merely to what is termed irritability, which does not cease immediately on the death of the animal. Eels have this peculiar property, that they are never out of season, though they are best in the summer months.

2208. *It is a curious fact in natural history that the manner in which eels breed is yet a problem not completely solved.* It has been generally said that they are viviparous; but Sir H. Davy observes, in his "Salmonia," "No facts are produced in proof of the assertion. It is certain," he says, "that shoals of very small eels are seen in the spring, making their way from the sea to the rivers; and that in the autumn great numbers are known to descend from the rivers to the sea. They even ascend the rivers over wet mossy rocks. In fresh water they fatten and grow large." The opinion of this acute observer was, that eels are oviparous, and deposite their ova in parts of the sea where they may remain warm in the winter, and that the young ascend rivers in search of food.

2209. *Ells were considered* by the ancient Romans as one of the most luxurious articles of the table. They were kept alive in reservoirs, and occasionally tamed to such a degree as to come at the signal of their master, in order to receive their food.

2210. *The Eel Pout*, or *Burbot*, is a fish much resembling the eel, and is found buried among loose sands, weeds, &c., in the Rivers Severn, Trent, and Mersey. They are sweet and nutritious: in length, from twelve to twenty inches.

Subsect. 24.—*The Minnow* (*Cyprinus Forinus*, Linn.).

2211. This is a very small fish, inhabiting rivers, and brooks, and canals, and chiefly known as affording amusement to juvenile anglers. They are of good flavour, and when a sufficient number can be procured by a casting net, make an excellent fry, somewhat like white bait, but rather luscious and cloying. In Walton's time, a dish called minnow tansies was made from them, now out of use. They were gutted, well washed in salt and water, and after their heads and tails were cut off they were put with yolks of eggs, well beat with cowslips and primrose flowers, and a little tansy shred small, and fried in butter; the sauce being butter, vinegar, or verjuice and sugar.

Sect. IV.—Shell-fish.

2212. Under this popular term we comprehend the two divisions of *crustaceous animals*, as lobsters, crabs, shrimps, &c., which have shelly coverings with feet; and *molluscous* *animals*, or molluscæ, as oysters, cockles, periwinkles, &c. These are now separated by naturalists from the class of fishes; they are in immense variety; many are used as food, but some of the naked molluscæ, or those without shells, are poisonous. Arranged under the genus cancer there is an immense number of crustacea in different parts of the world, but only a few species are found on the British shores.

SUBSECT. 1—*Lobster* (*Cancer Gammarus*, Linn.).

2213. *The common lobster frequents* all the northern seas of Europe. They are found on the rocky coasts of England and Scotland, but chiefly where there is a depth of water. Vast quantities are brought to London from the northern parts of Scotland, and particularly from the Orkney Islands, in smacks that have wells for keeping them alive. They are still more abundant on the coast of Norway, from which the metropolis is well supplied at most seasons of the year. A recent traveller in Norway saw an export of 48,000 lobsters shipped for London within three months from one place; and a regular "English lobster company" has agents actively employed all along the coast. Occasionally, though rarely, lobsters are taken by the hand, or rather by a hook, from under hollow stones, at low water, but by far the greatest quantity are caught in a kind of trap formed of twigs and baited with garbage; these are fastened by a cord and sunk into the sea, and their place marked by a buoy.

Lobsters are highly prolific; 12,400 ova or eggs have been counted under the tail of one female, besides that which remained in the body unprotruded. The eggs are deposited in the sand, where they are hatched.

They change their shells annually. Previously to putting off their old one, they appear sickly, languid, and restless; and they acquire a new coat in a few days after casting off the former one. During the time that they are thus defenceless they seek very retired places, for fear of being attacked and devoured by such of their brethren as are not in that weak condition. The new shell is membranous at first, but hardens by degrees, and they grow in size while the shell is in this soft state. The circumstance of lobsters throwing off their great claws voluntarily is very surprising, but sufficiently authenticated. If taken or entangled by the great claw, they will sometimes part with it by a sudden jerk, and thus effect their escape. Pennant says that when irritated, as when it thunders, or when great guns are fired, they will lose their claws. And scarcely less extraordinary is the reproduction of these members, which grow again in the course of a few weeks after the mischance has happened; but the new claws are not quite so large as the former ones. In the water they can run nimbly upon their legs or small claws, and, if alarmed, can spring tail foremost to the surprising distance of thirty feet, and as swift as a bird can fly. They are extremely voracious, feeding upon any kind of dead fish, and sometimes on sea-weed.

2214. *Lobsters are certainly nutritive, but not so much so as is commonly supposed;* they are not very easily digestible, and therefore require condiments, of which the most proper are those usually made use of, vinegar and pepper. On certain constitutions they have sometimes pernicious effects, and are known to have occasioned eruptions on the skin, and other distressing symptoms of derangement. Great care should be taken that they be in good condition, and absolutely fresh. When stale they are undoubtedly unwholesome in a very considerable degree. The fishmongers in London generally underboil them, with a view to their keeping, in which case they are extremely indigestible. According to Dr. Kitchener, they come into season about April, and continue plentiful till the oyster season returns in the autumn.

2215. *Lobsters brought alive from the northern extremity of the island in smacks with wells* for the purpose are often much wasted on their journey; their weight, therefore, is one proof of their goodness: but to ensure their being fresh, it is best always to buy them alive, and to boil them at home.

2216. *The ova* or *eggs, called by the cook berries,* and sometimes the *coral,* appear under the tail of the hen or female lobster only, and are black when raw, becoming in succession nearly as large as elder-berries before they are all deposited; the lobster continues depositing them as long as any remain in the body; when boiled, they are of a beautiful red colour.

It is a common mistake to suppose that a berried lobster is always in perfection for the table. When the berries are large and brownish, the lobster will be found exhausted, watery, and poor. The male lobsters are preferred for eating, particularly during the winter: it is distinguished from the female, not only by its want of the eggs under the tail, but by a narrower back part to the tail, with a strong spine upon the centre of each of the transverse processes underneath it, which supports its four middle plates; the two uppermost fins within his tail being stiff and hard, while those of the female are soft, and her tail broader. The female is best for sauce, on account of her eggs. The bag in the body of the lobster, called the "old lady in her arm-chair," containing the bony teeth, is the stomach, and is not fit to be eaten.

In choosing lobsters that are boiled, select those that are of a middling size, and heaviest for their bulk: to know if they are fresh, try if the tail has a springiness and will flap back again when raised up.

2217. *The common sea crawfish* (*Cancer palinurus*) is similar in its general properties to the lobster, but is less esteemed.

SUBSECT. 2.—*The Crab* (*Cancer Pagurus*, Linn.).

2218. *The crab inhabits most of the rocky shores* of England, and is taken in the same way as the lobster. It is in the highest perfection for the table about Christmas. The same observations which were made with respect to the nutritive and other qualities of the lobster apply to this crustaceous animal. Besides the cancer pagurus, the crab, which grows to a large size, and which is the only one brought to the table, is called, in Scotland, a *parten*; there is another much smaller, and without hairs (*Cancer mœnces*), more frequent about the shore; but this is a very poor, watery animal, of a greenish colour, and eaten only by the more indigent classes of people.

Crabs are found under large stones at low water, and are taken with a long stick having a hook at the end. But, on a larger scale, they are caught on the coasts of England and Scotland, in water from three to five fathoms deep, by sinking wicker traps containing bait, consisting of heads and entrails of fish. Many are brought from Norway. The male crab has the claws larger than the female, and is therefore of greater value. The female has the apron large, broad, and easily opened: that of the male is much smaller and narrower.

The best crabs have a considerable roughness on their claws; those with smooth shells are not so good. The crab is peculiarly tenacious of life, and is capable of exerting a considerable degree of muscular power after it has been removed two days from its natural element. It is often alive and fit for the table when, to all appearance, it seems to be dead. If any spark of life remain, it will be exhibited by the creature's exertions to keep the apron closed with its claws.

Crabs, as well as lobsters, are apt to throw off their claws on the stimulus of any sudden fright or pain, and therefore it is the practice, though a cruel one, in boiling them, to put them into cold water, by which they die gradually as the heat increases.

Crabs are in season all the year, except the months of May, June, and July; and a few may be had good at any time of the year.

Our English crabs are entirely marine; but in other countries there are also freshwater species; and in tropical climates land crabs are plentiful. *The land crab of the West Indies* (*Cancer ruricola*) lives in the mountains, and inhabits clifts in the rocks, hollow stumps of trees, and holes which they dig in the ground. Once a year they march down in a body to the sea side for the purpose of depositing their spawn in the sea, and, having accomplished this object, they bury themselves in holes in the ground, and cast their shells. They are often found in this condition, and in a fattened state, and are then highly prized as a wholesome and delicious food. There are two varieties of the land crab in Jamaica, one white, and the other black. The black crab is found abundantly in the eastern and northern marshes of the island during particular periods of the year; it is of the blackness of the lobster, and of a very light and handsome shape, as compared with any other species; it is very active upon its legs, and runs fast. The white land crab is very abundant in the low districts of the south side of the island: it is not so active in its movements as the black.

SUBSECT. 3.—*The Shrimp* (*Cancer Crangon*, Linn.).

2219. This lively little animal inhabits most sandy shores in Europe. It is too well known to the cook to require any description. As they are sold in London, they have almost always a great quantity of salt to make them keep, which overpowers their delicate and fine flavour. The Isle of Wight is famous for shrimps, where they are potted; but those prepared for London are generally too much salted.

2220. *The Prawn* (*Cancer squilla*, Linn.) is very analagous to the shrimp, but larger, finer, and less common.

SUBSECT. 4.—*The Oyster.*

2221. Oysters are almost universally distributed near the shores in all latitudes, and abound on the coasts of Britain and France, where they form a very important article of food. There are a great many species of oysters in other countries, but all those on our shores that go by the name of the common oyster belong to one species, the *Ostrea edulis* of Linnæus.

The nervous system of the animal is limited to the faculties of sense and touch, no especial organs for seeing having been yet discovered. Each oyster is perfect of itself, that is, capable individually of reproducing its kind.

2222. *In the breeding season*, which is in May, June, and July, the ovary is filled with a milky fluid, which contains a great number of ova, or eggs, of a whitish colour. Oysters are extremely prolific, and the young ones in the ova may be seen by the microscope floating in a viscid liquid. In May or June the young have reached their full size, leave the ovaries, and are then called by the fishermen *spawn* or *spat.*

Oysters adhere not only to rocks, but to any solid bodies that their spawn may light upon when cast, as small stones, wood, sea-plants, old oysters, or other shells, and a thousand things which are found at times with oysters growing in them. The spawn appears at first as a viscid matter, and is in great abundance; but much of it is destroyed by fish and crabs. The material at the bottom of the sea, to which the spawn adheres, is called by the fishermen *cultch;* and they are careful not to destroy it. Places that abound with sea-weeds or mud are not favourable to the propagation of oysters. It is conjectured that in twenty-four hours the spat begins to have a shell.

If an oyster happens to be cast on shore, it soon dies; but if deposited in places which are flooded at high water, they will keep their shells closed when it ebbs, and thus preserve their existence. When oysters are recently taken up from places that are never left dry by the sea, they open their shell, lose their water, and die in a few days; but kept in reservoirs in which they are left occasionally by the sea, exposed to the rays of the sun, or to severe cold, or when they are disturbed in their beds, they acquire the habit of keeping the shell close when they are uncovered with water, and exist without injury for a long time.

2223. *Oysters, being fixed to the rock, or some solid body, are usually supposed to have no power whatever of locomotion; nevertheless, it is said that they do possess this in a small degree*, by means of an organ called the foot, which is composed of various layers of fibres, that by their contraction bestow on it the power of motion. A very strong muscle, which is always cut across when the oyster is opened with the knife, named the adductor muscle, is attached to the interior opposite sides of the valves or shells; when this muscle is in a state of contraction, the shells are kept closed, and when the muscle relaxes, the shells open. When the animal dies, this muscle, of course, loses its power, and the shell gapes.

The oyster has many enemies which prey upon it, notwithstanding its shelly defence: the asteria, or sea star, clasps its arms or rays round the shell, and forces it open: crabs and lobsters are also destructive to a bed of oysters.

2224. *Oyster shells are composed* of carbonate of lime, cemented by animal matter of an albuminous nature: in some places they are burned for lime. A century ago they were employed medicinally calcined, though they are now considered as no way different from any other carbonate of lime.

2225. *The oyster fishery* is so important in Britain that it is regulated by the Admiralty Court. In the month of May, the fishermen have liberty to take every kind of oyster, whatever be their size. When they have collected them, they gently raise with a knife the small brood from the cultch, and then they throw the latter in again, to preserve the ground for the future, unless they have so much spat that they cannot be severed from the cultch, in which case they are permitted to take the stone or shells which the spat is upon, one shell having often twenty spats. The spat is then carried to creeks of the sea, where the water is still, and thrown there in order that they may grow large and fat, and that they may be easily obtained when wanted. In eighteen months they are grown sufficiently to be brought to market, but are not in perfection till about two or three years. The oysters are sick after they have cast their spawn in May, and they are then unfit for food; in June and July they begin to mend, and in the beginning of August they are recovered: on the fourth of that month they are permitted to be brought to the London market. All the winter they continue to be taken, and the oyster season terminates on the 12th of May.

2226. *The oysters fattened in artificial beds* are young, and generally reckoned the most delicate; but some persons prefer those that grow upon their native rocks, as having a higher flavour. Although oysters are among the natural productions of our coasts, yet this source is not entirely depended upon; but young oysters, of a size not exceeding a penny-piece, are obtained from various parts, and carefully planted in the artificial beds. The method of forming these artificial oyster-beds was known to the ancient Romans, who were exceedingly fond of this fish. The beds are mentioned by Pliny as the invention of one Sergius Orata. It is not a little remarkable that the finest oysters eaten in ancient Rome were fed in the channel which then separated the Isle of Thanet from England, and which has since then been filled up, and is now converted into meadows. It is extremely probable that the custom of forming oyster beds has been continued on our coasts ever since. Oysters have been reared in beds, ever since the times of the Romans, in the Lake Facino, on the coast of Baia near Naples, as described by Count Lasteyrie; this lake communicates with the sea by a narrow passage; along the margin of the lake are placed circles of reeds, with their summits above the water; the spawn of the oyster attaches itself to these reeds, and grows there till of an edible size: the reeds are pulled up and examined, and the full-grown oysters are removed, and put into he reserve till wanted: the small-sized and spawn are, with the reeds, put back again. It requires two years before the oysters come to their full size.

2227. *The means adopted for fattening oysters*, when transplanted, is one of the chief causes of their excellence. Nearly all the oysters brought to London have been so improved. The breeding-places are generally held on leases by a copartnery, consisting of a considerable number of individuals; and disputes often occur between the lessees of an oyster-bed and the fishermen. In some places, the latter contend that unfair modes of dredging are practised; and also that from those parts of the coast where no peculiar rights exist, the brood is carried away and planted in the beds, which are protected by law, thus making the weaker party contribute to the success of those who are already in possession of many important advantages.

It is certain, however, that the protected beds are a much more productive source of profit, both to the dredgers and to the public, than those which, from various causes, are left at the mercy of parties who are not locally interested in their preservation. In England, the oysters from the beds at Milton, in Kent, forty miles from London, are in high repute, as the whitest and most delicate, and are consumed in every part of England under the title of "native oysters." The native oysters are properly those that are born and bred in this country; and the Milton natives are mostly spat in the Burnham and Mersey Rivers, and placed in the Milton beds: they do not come into their finest condition till near four years old. The beds at Colchester, Pyfleet, Milford, Maldon, Feversham, Queensborough, Rochester, and those in the Swale and Medway, are also highly esteemed, and help to supply the London market. The common or Colchester oysters come in the 5th of August; but the native Miltons do not come in till the beginning of October, and are in greatest perfection near Christmas. There are also beds in Jersey and on the coast of Wales, which produce large quantities of oysters, some of which are brought to London.

On the Scotch coast oysters are less numerous than on the English, and they are not so frequently reared in beds; but the beds in the Firth of Forth and in Musselborough Bay, taken near the salt-pens, yield oysters of good flavour and of a large size. The Carlingford oyster, on the coast of the county of Louth in Ireland, are said to be of very superior flavour. Oysters from Brittany have been long famous, particularly those from Caucalle, near St. Malo; but those brought from Mercunes in Saintonge are in the highest estimation with the French. The green oysters eaten in Paris are brought from Dieppe. In tropical regions the common oyster is found attached to trees that grow on the edge of the sea, as the mangrove; and though this has been often thought fabulous, it is perfectly true. Many of the branches of these trees grow under water, and are covered with oysters. Instead of taking off the oysters, the branches are sometimes cut off with the fish upon them, carried home in baskets, and placed upon the table in that state.

2228. *Oysters are now most generally eaten raw, and in this state they are every way preferable.* When cooked, they are deprived of their salt water, which promotes their digestion, and they likewise lose much of their nutritive mucilaginous matter, their albumen becoming hard. When good, they are allowed to be, in general, highly nutritious; and with most persons they constitute an extremely light food; but with weak stomachs they are cold, and require the addition of some stimulant; pepper is the best.

2229. Oysters which have been fattened in artificial beds sometimes acquire a green tinge; and it has been supposed that this colour is occasioned by their having grown upon rocks impregnated with copper, and that such oysters, consequently, have a poisonous quality. As this is a popular error, it is proper to set the matter right. The green tinge is not owing in any instance to copper, but is derived, according to some, from the oysters feeding upon the minute plants, called confervæ, that grow abundantly in those places where the water is shallow and the sun has great power; the green colour is thought to be owing to a peculiar state of the bile. Oysters may be made green in such places in three or four days. When persons have been made ill from eating such oysters, they would, in all probability, have experienced the same effects from eating an equal quantity of any others. There are no rocks whatever containing copper in the places where our oysters are taken, nor can the slightest trace of copper be detected in them by chemical tests. The popular notion that oysters possess aphrodisiac properties appears to have no foundation.

2230. *Like all fish, they are out of season at spawning time;* and hence the origin of the old saying that "an oyster is never good except when there is an R in the month;" but this supposes that they are not to be eaten in August, and some are of opinion that they are not thoroughly fit till the beginning of September. During the period from the 12th of May to the 4th of August they are prohibited being taken or sold, in consequence of their being considered as unwholesome, the clerk of Billingsgate being empowered to seize and destroy all that are there offered for sale within the jurisdiction of the lord mayor. The magistrates of Rochester and Milton, however, not being empowered to proceed against the offenders, an illicit trade is carried on there.

2231. *During the season, the consumption of oysters* in London is immense, and no article of diet is more generally used by every class. The number of dealers is proportionably large, the poorest streets not being without one or two, generally supplied, at least, with the large but less delicately flavoured oyster.

They are kept alive for consumption for several days, or a week, in tubs containing water in which a quantity of salt is dissolved, with a little oatmeal added, for the oysters to feed upon, and thus be in condition. They are sent into the country, packed close in small barrels at the beds. Frequently what is sold as barrelled oysters are merely the smallest natives, selected from the stock and put into the tub when ordered; and, instead of being of superior quality, they are sometimes very inferior. At Billingsgate they are sold out of boats which lie alongside the market, in quantities not under one peck; and at the opening of the season the line of dealers extends all along Thames-street and over London Bridge. Many are exported to Holland, Germany, and other parts of the Continent.

SUBSECT. 5.—*The Scallop* (*Ostrea Maxima*, Linn.).

2232. The shell of this fish is well known as that which was formerly worn on the hat or coat by the pilgrims, as a mark that they had crossed the sea for the purpose of paying their devotions in the Holy Land; and in commemoration of this it is still preserved in the arms of many families. It is a *pecten* in the system of Lamarck, and is a very elegant shell, of a great variety of colours, acquiring the size of five or six inches across. It lies at the bottom of deep water, in beds, from which they are dredged up. The fish is very palatable, though of a peculiar flavour, and seldom eaten but in the fishing towns. It is boiled, roasted, or baked, or pickled in vinegar.

SUBSECT. 6.—*The Muscle* (*Mytilus Edulis*, Linn.).

2233. *The muscle is found* adhering to rocks by a strong silky beard, frequently in such quantities as completely to cover them. Since many persons who have eaten muscles have suffered severely, these fish are generally supposed to be occasionally poisonous. The cause of this does not appear to have been sufficiently ascertained. Some pretend to take out the part which they suppose to be deleterious, namely, a dark substance, and, in fact, the heart, which is perfectly harmless; others speak of the beard as indigestible. Lately, M. Bremnil is said to have discovered that the poisonous property of muscles depends upon the presence of a minute star-fish which enters into the shell in summer, but is never found in it in winter. He collected some of these star-fish, and gave them to dogs, upon whom the same symptoms were produced that appear when poisonous muscles are eaten. There are likewise fresh-water muscles, but they are never eaten with us.

SUBSECT. 7.—*The Cockle* (*Cardium Edule*, Linn.).

2234. The common cockle is a bivalved shell-fish found on all the sandy shores of Europe. Cockles bury themselves in the sand, out of which they are dug. They have a peculiar and agreeable flavour, and form an extremely wholesome food. They vary considerably in size on different coasts, and are very large on some of the Scottish shores. They are eaten boiled, plain, or fried, and are frequently used for sauce instead of oysters. Some have described them as of difficult digestion; but this does not appear to be the fact, from their universal use and general good character.

SUBSECT. 8.—*The Razor Fish* (*Solen Siliqua*, Linn.).

2235. This is a bivalved shell-fish, so called from the shells having nearly the form of the handle of a razor; it is only found on some particular coasts, and burrows in the sand. It is about six or seven inches long, and about one inch broad, the hinge being on the middle of the side. When the two shells are closed, they resemble a tube open at both ends. Part of the fish is of a cylindrical form, white and firm. They are eaten boiled or fried, and are very delicate and wholesome, although, perhaps, not very digestible.

SUBSECT. 9.—*The Periwinkle and Whelk.*

2236. These are well known univalved molluscæ, of little importance as general food, though eaten by the poorer classes, and sufficiently wholesome.

SUBSECT. 10.—*Helix Pomatia.*

2237. *A large species of land snail having a shell, called Helix pomatia*, is regularly bred and kept in gardens on the Continent for the table. In Germany, particularly in Vienna, sacks of these molluscæ are brought to the markets and sold; they are there considered as great delicacies. The enclosure in which they are kept is surrounded by boards, having the upper edge covered with small iron spikes, over which the snails never attempt to pass. They are fed upon cabbage leaves. This article of food was highly prized among the ancient inhabitants of Italy. The Romans bred them in prodigious numbers, fattening them in places called *cochlearia*, a particular description of which is given by Varro; and Pliny informs us that the method was invented by Fulvius Hirpinus, who lived a little before the time of Cæsar. This luxury grew to such a height that it was restrained by a special law. The Helix pomatia, or "esculent snail," was first introduced into England from Italy by a branch of the Howard family, one of the daughters of which, when labouring under consumption, having been recommended to eat soup made of it. Its medicinal virtues are, however, disregarded by physicians. These snails are not common in our fields, but are found at Boxhill, and in the vicinity of Dorking in Surrey. They are never brought to table with us.

Sect. V.—reptiles.

2238. Of reptiles, though some are among the luxuries of the table, yet the greater number are of little value for this purpose; and many are so disgusting in their appearance as to excite a strong prejudice against them; but none of them are known to be of a poisonous, or even unwholesome nature. Various species of *turtle* are well known. Of the lizards, the *dracæna* and *squana* form excellent food; and the *frog* supplies a favourite dish to our continental neighbours. The flesh of reptiles in general is delicate: the largest muscles are white, and contain a great deal of gelatinous substance: even serpents and snakes of all kinds, whether poisonous or not, are used as food by various nations. The poison of the serpent lies only in some receptacles attached to the fangs in the mouth; if the head be cut off, the body is innocent food. The *boa-constrictor* is considered as a great delicacy: the *rattlesnake* is broiled like eels by the North American Indians. *Viper broth* is known among us, and was formerly recommended as a restorative, although perhaps it is not superior in this respect to what is made from eels.

2239. *Turtle.*—Of the genus *testudo*, some inhabit the sea, and are called turtle; others are named tortoises, and live on land, or in fresh water.

There are several species of turtle used as food; but the best and most celebrated is called the *green turtle* (*Testudo Myas*, Linn.) from the colour of its fat. This turtle, so much prized as delicious food, is a very gentle and harmless animal, and sometimes grows to a great size, weighing from fifty pounds to five or six hundred weight, and measuring five or six feet in length. They abound in the seas of hot climates, particularly along the coasts of Cochin China and the islands of the East and West Indies, and frequently ascend the mouths of rivers. At the Isle of Ascension fifty have been taken in a week. Turtles are only calculated for swimming, the feet being so formed as to resemble a kind of fins or paddles, and they can move on land only with difficulty; nevertheless, they contrive to come on shore, and scratch holes in the sand to deposite their eggs, which they leave, after covering them up, to be hatched by the sun; in about a month the young ones come out and crawl to the water. The eggs are numerous, often amounting to above 100; and the female lays three times in a year: they are generally about the size of a small hen's egg, but sometimes much larger; they are quite round, consisting only of a yolk enclosed in a soft skin like parchment, are very delicious, and are highly esteemed. One of the usual modes of *taking* the turtle is by turning them on their back when they come on shore, from which position they cannot recover themselves without great difficulty. They are likewise caught while lying asleep on the surface of the water, and sometimes they are struck with the harpoon.

Turtle comes to us from the West Indies, some of the ships being provided with proper accommodations to permit them being brought alive and in tolerable health; but frequently they become emaciated during the long voyages, and then are very inferior for soup. There are various modes of cooking this excellent and nutritious food: one of the most usual methods in the West Indies, and perhaps the most wholesome, is to dress the flesh by boiling or frying like a beefsteak. It is also stewed, and made into the well-known turtle-soup, for which we refer to Book XIII., "Recipes in Cookery." What is called the green fat of the turtle is, in fact, not fat, but a gelatinous substance like the skin of a calf's head, or the tendons of the heel: that which forms part of the upper shield of the animal is called *callipash* by the cooks; and what belongs to the lower shield is the *callipee*. These are considered as the *bonne bouche* of the turtle. The flesh of the turtle is seldom dressed in the London taverns in any other way than in soup; occasionally as a steak. Turtle soup, as it is usually prepared here, is apt to disagree with dyspeptics.

Turtle is often a valuable addition to the live stock at sea; and the flesh may be salted and preserved a long time; in this state it is much used in the West Indies and America. Like other oviparous animals, turtles are best in season when beginning to lay their eggs; those which are full of eggs are reckoned the finest; after this, they are out of season. The introduction of this animal into England as an article of luxury is of no very distant date, and can perhaps scarcely be traced farther back than about 70 or 80 years.

2240. *The loggerhead turtle* (*Testudo Caretta*, Linn.) is often larger than the green turtle, and its shell is beautifully coloured, but too thin for manufacture. It is a strong and fierce animal, and even dangerous: it is found in the Mediterranean, but its flesh is coarse and rank.

2241. *The elegant substance known by the name of tortoise-shell* is made from the shell of a variety of turtle called the *hawksbill*, or *imbricated turtle*, which is a native of the Asiatic seas, but found, though much more rarely, in the Atlantic, and even in the Mediterranean. Its general length is about three feet, and the shell is formed in scales that lap over each other like the tiles of a house. The flesh is said to produce fever and dysentery, but the eggs are wholesome. It is a ferocious creature, and defends itself with vigour.

2242. *Tortoises* are of two kinds: the land and fresh-water tortoise. The land species is distinguished by club-shaped feet, and toes furnished with claws, and has the shell very convex. The fresh-water species have their feet more or less webbed.

2243. *The common land tortoise* (*Testudo Græca*, Linn.) receives its name from abounding in Greece and the countries bordering on the Mediterranean. It is covered by an extremely strong shell, about seven inches in length, and weighs about three pounds. It is a slow, stupid-looking animal, lives upon milky plants, as lettuces, dandelions, &c., delights in warmth, but avoids the heat of the sun in summer, and is equally afraid of rain. In the winter he burrows into the ground, where he remains torpid for some months. Its flesh is eaten by the inhabitants of those countries where it abounds, and likewise its eggs, which it lays in holes in the earth, where they are hatched by the sunbeams. It is well attested that this animal lives to a most extraordinary age, several examples being adduced of its having considerably exceeded the period of a century. One of the most remarkable instances is that of a tortoise introduced into the bishop's garden at Lambeth, in the year 1633, which continued to live there till 1753, when it was supposed to have perished rather from accidental neglect on the part of the gardener than from the mere effect of old age. Its shell is preserved in the library of the palace at Lambeth. The tortoise can refrain from eating as well as breathing for a great part of the year; and, from some experiments made upon it, appears to be tenacious of life in a most extraordinary degree, living and walking about for six months even after being deprived of its brains, and the body lived for twenty-three days without the head.—*Shaw's Lectures.*

The land tortoise occurs in great numbers in various parts of Hungary, more particularly about Fuzcs-Gyarmath, and the marshes of the River Theiss; and being esteemed a delicacy for the table, is caught and kept in preserves. The preserve of Keszthelev encloses about an acre of land, intersected by trenches and ponds, in which the animals feed and enjoy themselves.

2244. *The mud tortoise* (*Testudo lutaria*, Linn.) is rather less than the last, being about seven inches long, and, though rather an aquatic animal, lays its eggs on the ground. It is common in many parts of Europe and Asia, particularly in France, where it is used as food. It moves quicker than the land tortoise; feeds upon vegetables, milk, worms, or offal, and is frequently kept in gardens to clear them of snails. It is destructive to the fish if it gets into a fish-pond. The flesh is considered as restorative, and useful in warm climates, where in summer the cattle are thin from the irritation of insects, and the poultry rank from the quantity of worms they pick up.

2245. *The river or fresh-water tortoises* are more rare: one of the most remarkable is the *Testudo ferox*, or fierce tortoise, a native of many parts of North America; its head is small, and its neck very long, which it withdraws within its shell. It is an animal of swift motion, and will spring forward with great fury to attack its assailant: the usual length from one to two feet, and it is web-footed. The flesh of this is not inferior to that of the green turtle.

2246. *The crocodile* is eaten by the natives of some parts of Africa; but European travellers, who have tasted its flesh, describe it as having a nauseous musky taste, though some parts are more delicate, resembling veal.

2247. *The guana*, or *iguana*, is a lizard four or five feet long, an inhabitant of South America and Africa, and sometimes met with in the West Indies: it is gentle and harmless, and so much prized on account of the delicacy of its flesh, that it has become rare in many places where formerly it abounded. Stewed guana is a favourite dish in the West Indies. Its eggs are a great dainty.

2248. *Various other lizards* are eaten in different parts of the world, and none of them are injurious as food.

2249. *The frog* (*Rana*, Linn.), which is so frequently eaten in France and many parts of the Continent, and which we hear so much about, is not our common frog, but another species somewhat larger, the *Rana esculenta*, Linn. It is of a green colour, spotted with black, and having two pale yellow lines down the back. It is the hind quarters only that are eaten, and these are more fleshy than the thigh of our common frog, resembling the most delicate chicken; when fricasseed or made into patties, it makes a most excellent dish, which, however, in Paris is by no means cheap. The livers and fore legs are used in soup. They are brought alive in thousands to the capital cities of France, Belgium, Germany, and Italy, and in some places there are regular conservatories for keeping them alive. This frog is rare in England.

2250. We are told by Montfort, a French naturalist, that frogs are much in request at Vienna, where not only the thighs are eaten, as in France, but every part of the animal. At the commencement of winter the dealers in these creatures fill a pit with thousands of frogs, which the country people collect in the marshes and ponds, and cover them with straw and planks to keep them from the frost. In this manner they are preserved alive to supply the market as required, and there are few individuals who in the winter season do not occasionally regale themselves with a few dozen of these reptiles, which are made into dishes highly prized by the gourmands. There are even some houses where they may always be had in the choicest condition, dressed with the greatest care, and sold at a great price.

2251. *The common frog* is much inferior, but is also eaten occasionally, and is sometimes fraudulently substituted for the other species.

2252. *The bull frog* (*Rana taurina*, Linn.) of warm climates is considered equal to the turtle.

2253. *The toad* is often here supposed to be poisonous, though this is doubtful: it is a very harmless creature; but, from its ugliness, excites disgust, and is not desired as food. Among the negroes, however, it is said to be eaten without any bad consequences.

2254. *Insects.*—Few insects are used as food. The *locust* is, however, consumed in great quantities, which affords some compensation for the ravages it occasions. In Abyssinia, and among the Moors of Barbary, they are eaten both fresh and salted, and some are dried in the sun. Niebuhr informs us that in Arabia they preserve them in the same manner, and they consider them a delicacy, their taste resembling that of a crayfish. Among the natives of South Africa they are made into a kind of soup. Diodorus Siculus describes the natives of Ethiopia as feeding upon locusts. This explains what we are told of John the Baptist, who lived upon locusts and wild honey. Many insects, however, are of a poisonous nature, and it is remarkable that, as we descend in the grades or classes of animals both of land and sea, the number increases of those which are un fit for human food.

CHAPTER VII.

ON VEGETABLES USED AS FOOD.

SECT. I.—GENERAL VIEW OF THE CONSTITUTION OF VEGETABLES.

2255. *The larger portion of the food consumed by the human race is, perhaps, derived from the vegetable kingdom.* We learn from the sacred writings that vegetable food was the first employed by mankind; and ancient profane writers, as Diodorus Siculus, Ælian, and Pliny, represent the primeval races of mankind as ranging over the fields and woods in search of fruits and wild herbs. Wild pease and acorns are mentioned as constituting the greatest part of the food of the first inhabitants of Greece. The cultivation of corn, which is by Hesiod ascribed to Ceres, was an important step in civilization; and divine honours were paid to her on that account. In warm climates, fruits and other kinds of vegetable nutriment are produced spontaneously in great abundance, and several nations at present subsist almost solely upon this diet.

2256. *Only a small part of the numerous tribes of plants are, however, available for food in their natural state:* unlike the animal kingdom in this respect, the greater number of vegetables are useless as food, and many are extremely deleterious. The choice of vegetables, therefore, for this purpose requires more precaution than that of animals. Botanical knowledge can often point out those which may be considered as poisonous, and those which may be safely eaten; but in meeting with new or undescribed species, great caution should be used, and it may be prudent first to try their effects on quadrupeds.

Although nature supplies the inhabitants of tropical regions with abundance of vegetable food, almost without the trouble of cultivation, yet that is not the case in temperate climates. Almost all the esculent vegetables which are found in Europe have been introduced from other regions by the industry of man, and many of them may almost be considered as the produce of art, since they have been gradually brought to the state in which we now see them by the gardener and agriculturist, who, by cultivation, have metamorphosed certain wild and unsavoury herbs into the delicious and varied produce of our gardens. Many of these changes have been brought about at a very early period in the history of mankind; for instance, the originals from which the varieties of cerealia, or corn plants, have been derived, cannot now be traced by the botanist in their wild state; and yet corn supplies all the civilized world with its chief article of food. Here we perceive the advantages which have accrued to mankind from the employment of their reasoning faculties. The whole of our cabbages and cauliflowers, whose leaves alone often weigh several pounds, have been acquired by the gradual transformation of the wild colewort, a plant of scanty leaves, not weighing more than half an ounce. From the sour sloe has been produced the delicious plum, and the austere crab has been transformed into an almost endless variety of apples, possessing the richest flavours and the utmost beauty of colour.

2257. *Some vegetables undergo extraordinary changes* at different periods of their growth. While young, they may be safely eaten; yet when they attain such an age that they are capable of reproduction, they possess properties which render them poisonous if employed in the same manner, though they may be used as active medicines in small quantities.

2258. *Different species of plants vary exceedingly according to the parts which afford wholesome and proper nutriment.* In some this is found only in the seeds; in others in the leaves; in some, again, in the roots; of others all the parts may be eaten. Some are even poisonous, until they are deprived of a certain juice, and then the rest is harmless food.

The fibrous and membranous parts of vegetables are not easily digestible, or not at all. The skins of fruits in general, as of grapes, pass through the stomach unchanged; so do the husks of pease; and corn, grains, or seeds of various kinds, often go through the stomachs of horses, birds, and other animals in a state still fit for germination, on account of the indigestibility of the husks, which points out the advantage of first boiling or soaking them in hot water till they burst. The green leaves of vegetables, though in general acting somewhat on the bowels, are apt to produce acidity and flatulence with dyspeptic persons, and are therefore less fit for them than farinaceous food.

2259. *Vegetables, though devoid of sensation, possess what is termed the living principle;* but this is of a very different kind from what we denominate the life of an animal; yet between both there are analogies which are very remarkable. Animals receive food into their mouths, from which it passes into the stomach; plants take in their food by the roots, which are their mouths. Both animals and vegetables possess a power, depending upon the vital principle, by which the food is digested, converted into nutriment, and assimilated, so as to enter into the substance of their frames. In order to this, it is made to move through a series of vessels, in which it undergoes certain alterations, by which it is transformed into several different juices adapted for different purposes in the living body. The mode in which these changes are effected is absolutely unknown to us, the chemistry of nature being beyond our power of investigation. But by these means are formed all the substances called *secretions*, whether gum and sugar in vegetables, or bile in animals. Plants are even provided, as well as animals, with a breathing apparatus, consisting of an infinity of minute pores which open upon the surface of the leaves, and communicate with the tubes that contain the flowing juices; and in both cases air is essential to the life and health of the organic being. Not only do various plants secrete different substances, but they require different kinds of food, and various temperatures, in order to flourish, as is the case with animals. Notwithstanding these points of agreement, however, the difference between the two classes is sufficiently marked in general, although certain species in each approach so near together that it is sometimes difficult to say to which of the two kingdoms they properly belong.

2260. *In considering the nature of vegetable matter as employed for food,* we shall follow the same plan as that by which we examined the nutritive properties of animal food. We shall inquire into the chemical nature of vegetables in general, and collect together those *proximate principles* into which all vegetable substances may be resolved.

2261. *It has been already stated that the elements of which all vegetable bodies consist* are carbon, oxygen, hydrogen, and nitrogen.

But nitrogen exists in the vegetable kingdom in much smaller quantity than in animals. This constitutes a marked difference between animal and vegetable matter. The former has *always* a large proportion of nitrogen in its composition; whereas, in the latter, this element is found in any considerable quantity only in particular parts of plants, as, for example, in their gluten and albumen; in many other parts it is entirely wanting, a few vegetables, as the fungi, which abound in nitrogen, being exceptions. Thus (as we have already stated, but which we here repeat for the convenience of the reader) the same elements are found both in the animal and vegetable kingdom; and the very same particles may at one time compose part of an animal, and at another time be a portion of a vegetable. There is not, therefore, as some persons might suppose, a kind of substance absolutely and permanently of a vegetable nature, but matter is only vegetable for a time. Thus, animals feed upon vegetables; and the elementary particles of which the latter consist enter as food, and are made to supply the waste in animal bodies; the particles unite with the animal substance, and become of the same kind; they are assimilated, and are now a portion of an animal. The animal dies, undergoes decomposition, and its carcass, or a part of it, mixes with the soil, and is often employed as manure to vegetables. A portion of the decomposed animal matter acts either directly or indirectly in supplying food to the roots of the plant, which it forms into wood, bark, juices, or other parts of its body. In this new condition, the particles may belong essentially to the vegetable: but they have suffered no actual change; they have only been arranged in a new form, and are differently combined. The elements we have mentioned as common to the two kingdoms are exactly of the same nature, whether they are drawn from the one or the other. But nature only can make these arrangements: human art can decompose both animal and vegetable matter into its ultimate elements, but cannot form out of them either an animal or a vegetable, nor can it change the one into the other. Nature, in forming vegetable matter, or vegetable arrangements, follows the same plan as when composing animal matter: in both cases, *proximate principles are first composed;* but the proximate principles of vegetables are different, except a few, from those of animals.

2262. *By what means plants compose their proximate principles* out of the four elements is a mystery which we cannot penetrate; it must be classed with the incomprehensible functions by which they increase and propagate their species, and with those laws by which they continue to present the same forms and qualities through innumerable generations: phenomena which cannot fail to impress upon the mind of the careful inquirer a conviction that the whole is regulated by causes and powers far transcending our limited capacities to explain, and demonstrating an omniscient and superintending Providence.

We shall, therefore, in studying vegetable substances, have to enumerate a set of bodies called *proximate principles*, belonging to the vegetable kingdom, generally distinct from those appertaining to animals. All these exist ready formed in the plant, in the same manner as in the case of animals; and all vegetables may be resolved first into these before their final dissolution into their elementary constituents, carbon, oxygen, and hydrogen.

2263. *The proximate principles of vegetables are:*

1. Starch, or fecula.
2. Gluten.
3. Vegetable albumen.
4. Sugar, or the saccharine principle.
5. Gum, or mucilage.
6. Lignin, or woody fibre.
7. Vegetable jelly, or pectin.
8. Vegetable oils, fixed and volatile.
9. Vegetable wax.
10. Resin.
11. Balsams.
12. Gum resins
13. Camphor.
14. Tannin, or tannic acid.
15. Colouring matter.
16. Vegetable acids.
17. Vegetable alkalies.

The first five of these principles, viz., starch, gluten, vegetable albumen, sugar, and gum, constitute the principal ingredients in most of the esculent vegetables; and starch and gluten are much more nutritious than the rest.

2264. *The comparative nutritive properties of the several vegetable substances* used as food is best known by chemical analysis. It having been already determined by long observation which of the vegetable proximate principles afford the most nourishment, or tend most to the support of life by the process of digestion, chemical analysis will, by showing the relative proportions of these principles in each species of plants, enable us readily to distinguish which kind is most nutritive.

Vegetable Substances.	Whole Quantity of soluble or nutritive Matter.	Starch or Mucilage.	Saccharine Matter.	Gluten or Albumen.	Extract or Matter rendered insoluble during Evaporation.
Middlesex wheat, average crop	955	765	—	190	—
Spring wheat	940	700	—	240	—
Mildewed wheat of 1806	210	178	—	32	—
Blighted wheat of 1804	650	520	—	130	—
Thick-skinned Sicilian wheat of 1810	955	725	—	230	—
Wheat from Poland	950	750	—	200	—
North American wheat	955	730	—	235	—
Norfolk barley	920	790	70	60	—
Oats from Scotland	743	641	15	87	—
Rye from Yorkshire	792	645	38	109	—
Common beans	570	426	—	103	41
Dry pease	574	501	22	35	16
Potatoes	from 260 to 200	from 200 to 155	from 20 to 15	from 40 to 30	— —
Linseed cake	151	123	11	17	—
Red beet	148	14	121	14	—
White beet	136	13	119	4	—
Parsnip	99	9	90	—	—
Carrots	98	3	95	—	—
Common turnips	42	7	34	1	—
Swedish turnips	64	9	51	2	2
Cabbage	73	41	24	8	—
Broad-leaved clover	39	31	3	2	3
Long-rooted clover	39	30	4	3	2

Lucern	23	18	1	—	4
Meadow fox-tail grass	33	24	3	—	6
Perennial rye grass	39	26	4	—	5
Fertile meadow grass	78	65	6	—	7
Roughish meadow grass	39	29	5	—	6
Crested dog-tail grass	35	28	3	—	4
Spiked fescue grass	19	15	2	—	2
Sweet-scented soft grass	82	72	4	—	6
Sweet-scented vernal grass	50	43	4	—	3
Fiorin	54	46	5	1	2
Fiorin, cut in winter	76	64	8	1	3

2265. *The preceding table, drawn up by Sir H. Davy,* and published in his excellent work "On Agricultural Chemistry," exhibits the nature of most of our vegetables used commonly as food. To form it, 1000 parts of each vegetable were analyzed, and the table states the quantity of nutritive matter extracted, consisting of mucilage or starch, saccharine matter, gluten or albumen, and extract. The first column shows the entire quantity of nutritive matter, and the difference between that and the 1000 parts consisted of water, or inert or indigestible vegetable matter, possessing the properties of woody fibre.

2266. It must not be supposed that the above proportions are always exactly the same in the vegetables described in the above table, since much depends upon their cultivation and growth; yet they are probably never very different, and the results of the analysis offer some interesting facts. They show that wheat is the most nutritive of all the vegetables in common use among us, consisting almost entirely of starch and gluten, both of them highly nutritive principles. The other kinds of grain, as barley, oats, rye, as well as pease and beans, contain a more considerable portion of gluten than other vegetables, but much less than wheat.

2267. *There is one remarkable difference between vegetable and animal substances.* The attractive power or affinity by which the particles of the vegetable proximate principles are held together appears not to be so powerful as that by which those of animal bodies are united, for slight circumstances are sufficient to convert one vegetable proximate principle into another. Thus, gum, starch, and woody fibre may be converted into sugar or into acids; but no such change can be effected upon animal matter: we cannot convert fibrin into gelatin nor into albumen.

This easy conversion of vegetable principles into each other is important to attend to; for, in consequence of this, it is often supposed that vegetables contain what they do not; a substance may be apparently drawn from a vegetable, while, at the same time, it is very certain that no such substance exists in the plant. This error happens because, during the process employed, a change takes place in the arrangement of the matter acted upon, as may be exemplified in the case of obtaining spirit or alcohol from fermented barley or carrots. No spirit exists in barley, carrots, nor in any other plant; but the spirit is formed during the fermentation.

2268. *In considering the chemical constitution of the several proximate principles of vegetables, MM. Gay Lussac and Thenard have observed a curious law,* which, though it cannot be considered as positive or free from exceptions, is yet highly deserving of attention, as assisting us in forming general views, which are always important in classifying and arranging our knowledge.

First. Water is known to consist of hydrogen and oxygen only in fixed proportions; and certain proximate principles, as starch, gum, sugar, and woody fibre, which consist of carbon, hydrogen, and oxygen, have their hydrogen and oxygen in the precise proportion necessary to form water; so that, although we cannot say that these substances are composed of carbon and water, yet they consist of carbon and the elements of water in a triple combination: hence it follows that the composition of these four bodies is so nearly the same that chemists are somewhat at a loss to say in what the chemical difference consists, although they vary so much in their actual properties; but that there is a chemical difference no one doubts.

Secondly. If the proportion of *oxygen* in vegetable substances be more than is sufficient to form water with its hydrogen, that substance will be found to have *acid* properties; and all the vegetable acids are of this kind.

Thirdly. If they contain more *hydrogen* than is necessary to form water with the oxygen, then the bodies are either *oily*, *waxy*, or *resinous*. Thus we may perceive, in the proximate principles of vegetables, three great natural groups: the *saccharine*, the *acid*, and the *oily* groups; to which may be added a fourth—an *alkaline* group—distinguished by all the substances composing it, with a very few exceptions, containing *nitrogen* in addition to the other three elements.

These groups may be arranged as follows:

SACCHARINE GROUP.

Starch.
Gluten.
Vegetable albumen.
Sugar.
Mucilage.
Gum.
Lignin.
Vegetable jell

OILY GROUP.

Vegetable fixed oil.
Vegetable volatile oil.
Resin.
Gum resins.
Wax.
Camphor.
Extractive matter.
Bitter principle.
Caoutchouc.
Colouring matter.

ACIDS.

Acetic acid.
Malic acid.
Citric acid.
Tartaric acid.
Oxalic acid.
Gallic acid.
Tannic acid.

ALKALIES.

Soda.
Potash.
Quinea.
Cinchonia.
Strychnia.
Veratria.
Emetia.
Picrotoxia.
Solania.
Synopia
Atropia.
Conia.
Nicotina.
Hyoscyamia.
Daturia.
Colchica.

SECT. II.—STARCH.

2269. *This principle, which is also called Fecula, and the amylaceous principle,* from the Latin *amylum*, is one of the most important in the vegetable kingdom, as it constitutes the principal nutritious matter in all the farinaceous vegetables used as food. It is likewise chiefly owing to the starch of grain that malt is so well calculated for the purposes of brewing: in short, from its numerous uses, it is very necessary that we should be accurately acquainted with it.

2270. *Starch is a substance ready formed by nature,* and it exists in many plants, in the form of extremely minute globular or oval grains; but these are so small that they cannot be distinguished separately without the assistance of a very powerful microscope. These grains consist of a membrane enclosing the starchy or amylaceous matter; and it is said that they do not readily burst with the heat of the stomach, and that, on this account, all such substances, when used as food, ought to be boiled to produce this effect. When cooked, farinaceous substances (those which abound in starch) constitute food that is mild, nutritious, easily digestible, and little stimulating, consequently very fit for infancy, though not sufficiently strengthening for manhood. Starch is found in the roots of some plants, as potatoes; in the stems of others, as the palm, from which sago is extracted; in the seeds of leguminous plants, as pease and beans; but most of all, in the seeds of corn-plants, and chiefly wheat: in all these it is very nearly the same, and is united in them with gluten, mucilage, and saccharine matter.

To understand this, and some of the other important vegetable principles, a simple experiment may be made: Get some flour, and, keeping it in the hand, knead it well in a basin of cold water, while another person pours gently some more water over it until the latter no longer runs off milky and turbid. The substance that remains now in the hand will be a tenacious, elastic sort of paste called gluten, which we shall have occasion to describe afterward. If the water in which the handful of flour had been worked, and which is milky-looking, be suffered to stand still for a few hours, a very white sediment will fall to the bottom; this is the starch, which has been washed out of the flour. If the clear water standing over it be poured off, and boiled till it be nearly all evaporated, the thickened extract will be a mucilaginous substance, a little sweet; and it will contain the mucilage, or gum, and the saccharine matter of the flour. In this manner the several constituent principles of flour may be separated from each other for examination.

2271. *Common starch*, as it is found in the shops, is procured from wheat by a process nearly similar to what we have just described, and is the pure fecula we are treating of; but our object at present is not to describe the mode of its manufacture; this will be shown in Book XXII., "On the Laundry." The process for extracting the starch from any other vegetable is the same: they are all bruised and agitated in water, when the starch separates readily, and subsides; then, after standing some time, the clear water is poured off, and the starch is obtained. The starch procured in this manner from potatoes is essentially the same as that from wheat, differing only in a few slight particulars.

2272. *Starch, when pure*, is very insipid, or without taste, and of a brilliant snow-white. It will not dissolve in water, either cold or below 160°; but in water between 160° and 180° it forms an important solution, thickened into a gelatinous mass, which is the state in which it is employed for stiffening linen.

On exposing dried starch to a temperature a little above 212°, it acquires a slight red tint, emits an odour like baked bread, and is slightly soluble in cold water. When roasted in a flat vessel it becomes brown, and is converted into a substance called *British gum*, which is soluble in cold water, and used instead of gum by the calico-printers. Potato starch answers best for this purpose.

2273. *Starch, when decomposed*, or separated by chemical means into its ultimate elements, is found to consist, like most vegetable matter, of oxygen, carbon, and hydrogen; and, although it is so very different from sugar in its ordinary properties, yet, as has been already observed, it differs but little from that substance in the proportion of its constituents.

In consequence of this close analogy, *starch is very easily converted into a kind of sugar*, a fact, the importance of which will be perceived when we come to the subject of brewing, where we shall find that the formation of malt depends upon the change of the starch of the barley into sugar during the process of malting.

2274. *Starch has even been converted into this kind of sugar, in considerable quantities, by a very simple chemical process*, which consists merely in boiling it with a certain proportion of water and sulphuric acid. As this conversion is well calculated to illustrate some of the chemical changes which occur in several of the arts which we have to treat of, we give the details of the process in this place.

A pound and a half of potato-starch was kept simmering at a boiling heat in a mixture of six pints of distilled water and a quarter of an ounce (by weight) of sulphuric acid. The mixture was afterward stirred, and fresh water occasionally added to supply the loss by evaporation. After thirty-four hours an ounce of powdered charcoal was added, and the boiling resumed for two hours. The acid was then carefully saturated with lime, and the boiling continued for half an hour, when the liquor was strained through calico. The insoluble residue, after having been washed and dried, consisted of charcoal and sulphate of lime. The filtered liquor was evaporated to the consistence of sirup, and, being set aside, became in eight days a crystallized mass, resembling brown sugar and treacle. The sugar weighed a pound and a quarter. One pound of it fermented in the usual way, and afforded on distillation fourteen drachms of proof spirit.

This sugar from starch is not exactly the same as that made from the sugar-cane; it is less sweet, requiring two and a half times the quantity of cane-sugar to sweeten to the same degree, and it is not quite so soluble. It agrees in its properties with the sugar of grapes, and, like it, is capable of being converted into spirit by fermentation; it is, in fact, the very substance that affords the spirit in malt liquors. How the conversion of starch into sugar is effected is not very well understood, and we wish to avoid entering into theoretical views not yet quite established; but, as has been observed above, it is supposed that, the mutual attractions of the elementary principles of vegetable bodies being very slight, they are made to change their situations by very slight causes, and a very minute difference in their arrangement occasions a sensible difference of properties: a fact of which chemistry furnishes many examples. Few substances, indeed, appear at first more unlike than starch and sugar; the former is very insoluble and insipid, the latter very soluble and sapid. Since, as we have stated, the elementary principles, hydrogen and oxygen, exist in the proportion necessary to form water in starch, sugar, gum, and ligneous or woody fibre, these substances may be considered as so many compounds of the elements of water with carbon, the remaining element; and since, in the processes just described, the weight of the sugar obtained exceeds that of the starch employed by ten per cent., it has been supposed that the sugar is a chemical combination of starch with water.

2275. *Nature produces the change from starch to sugar during the germination of seeds in the earth.* When, under the proper circumstances of heat and moisture, germination has commenced, it will be found that the farina, or white internal kernel of the seed, has in a great measure disappeared, and that its place is supplied by a substance having a saccharine taste. It is this peculiar sugary substance that constitutes the food of the embryo plant, and it is for the purpose of supplying this food that nature has effected the change.

2276. *Man has imitated this process* in the malting of barley for the purpose of producing fermented liquor. When we treat of "Brewing and Distilling," this subject will be entered into more fully; at present it is merely hinted at, to bring all the points into the same view; and we shall then see, also, why all the substances possessing starch may also produce alcohol or spirit; first, by the conversion of the starch into sugar, and then the latter into spirit.

2277. *But starch, or fecula, cannot be always separated,* in the manner described above, from all the plants in which it exists. Sometimes it is intimately united to mucilage and oil, as in the case of the almond, and many other kernel seeds. In such plants, all these principles become diffused in the water in an equal degree on pressure, and the fecula will not be deposited by mere subsidence; nor can it, in this case, be obtained pure in any way under these circumstances.

2278. *Starch is an extremely nutritive material,* and constitutes one of the chief ingredients in almost all the most valuable vegetables used as food by man. In many instances it is not separated from the vegetables before being employed as aliment, but, in other cases, processes are employed to extract it distinct from the other ingredients, some of which are nutritious, and others injurious.

2279. By this means various species of food have been produced in foreign countries, and are in use among us, while few persons have an idea of their origin, or their relation to common starch. Of this kind are *arrow-root,* which is the starch extracted from the tubers of a plant that grows in the East and West Indies, the *Maranta arundinacea*; *sago,* a starch procured from the pith of several species of palms; and tapioca, made from the starch of *Jatropha Manihot,* a South American plant. *Tous les mois* is a substance of this class lately brought here from St. Kitt's, and said to be the starch of the *Canna coccinea.* All these boil to a jelly like starch, and are light and nutritive. They will be described more particularly in Chapter III., Book IX., "On Bread."

2280. *From the nutritious substances which have been just mentioned,* all of which consist of mere starch, we may perceive how very important is this principle in the vegetable kingdom; but this importance will be much increased when it is pointed out, as it will be when we come to the article "Bread," that it is chiefly the starch they contain which renders all the kinds of corn and leguminous seeds so valuable as food. In these, indeed it is combined with the other proximate principles, such as gluten, sugar, oil, &c.; but it is the starch, much more than all the rest, which constitutes the nutritious part of corn and other vegetables.

2281. *Starch has the remarkable property of assuming a blue colour,* by means of the substance called *iodine,* which is accordingly employed as a test for ascertaining its presence.

Sect. III.—gluten.

2282. In the experiment with wheat flour which was mentioned above, when starch was separated by washing, a viscid substance remained in the hand, which received the name of vegetable gluten from its discoverer, Beccaria, on account of its resemblance to glue. It is a gray, viscid, tenacious, and ductile substance, insoluble in cold water, that may be stretched out in a manner somewhat like Indian rubber. It is found more or less in a great variety of plants, but very abundantly in the kinds of grain used for making bread. Wheat contains the largest portion of it; and this is one reason why wheaten bread is superior to that made from other kinds of grain, for gluten is the most nutritious principle, though not the most abundant, contained in vegetables. It is the gluten in wheat flour that renders it so proper for light fermented bread, by occasioning its making a tenacious paste with cold water, the viscid elastic nature of which enables the carbonic acid disengaged during fermentation to form numerous vesicles that distend the mass of dough, and produce what is called the *rising.* This will be fully explained under the article "Making Bread."

2283. But it has been shown by Einhoff that the viscid substance which we have mentioned as obtained by kneading wheat flour is not pure gluten, but consists of gluten and another vegetable principle, called vegetable albumen. They may be separated from each other by boiling in alcohol, or by kneading them with the hand in alcohol; the latter being soluble, and the former insoluble, in it.

2284. *Pure gluten*, thus obtained, is of a full yellow colour, with a slight balsamic taste and a peculiar odour; it is very tenacious and elastic, and does not dissolve in cold water; but though gluten is so nutritive, it is only so when united with other vegetable principles, for by itself it is scarcely digestible. When kept moist in a warm place it ferments, and disengages carbonic acid, but afterward gives out acetic acid, which is the cause of the sourness perceived in leavened bread; in a few days, if left to itself, it acquires a smell and taste much like cheese, then it putrefies, and gives out an offensive odour like animal matter. When exposed to the air, it gradually dries, and becomes hard and brittle, like glue, from which property it has been employed to mend broken china. It loses its tenacity entirely by boiling. Gluten, though insoluble in water alone, forms a compound with acetic acid or vinegar that is soluble in water; and this is the reason why, in the manufacture of starch, just described, the souring, or formation of vinegar, acts upon the gluten that was united to the starch, and thus removes it from the latter.

Gluten differs from all the other vegetable proximate principles, except vegetable albumen, in containing nitrogen, of which it contains from 14 to 20 per cent., and this is supposed to be the cause of its being so nutritious.

SECT. IV.—VEGETABLE ALBUMEN.

2285. *Albumen has lately been discovered to be common to the vegetable as well as to the animal kingdom, though in a smaller quantity.* In its pure state it is a thick, glairy, tasteless fluid, analogous to white of egg. It is found abundantly in the juices of green leaves, as well as in the flour from wheat. It resembles gluten considerably in its composition, containing also nitrogen, but it is soluble in alcohol, and in cold water, which gluten is not. When the juice of cabbage leaves, or other similar plants, is pressed out and passed through a cloth, it is not at once transparent, but a fine green powder is suspended in it, which will require a week to settle to the bottom: this is called green fecula, and it consists of three substances: 1, a green colouring matter, which is resinous; 2, woody fibre that has been entangled in the juice; 3, vegetable albumen. If a glass bottle filled with the green juice as soon as it is filtered, and before it has time to settle, be placed in a vessel with boiling water, the liquor will deposite a flocculent or cheesy matter, which consists of the albumen, which has coagulated by the heat; and as it resembles the white of egg, when washed and deprived of colour, it has received the name of *albumen*, though not absolutely identical with animal albumen; it appears to be sometimes a vegeto-animal substance.

It can scarcely be necessary to state that this principle contained in the juice must coagulate in the same manner as animal albumen when vegetables are boiled; and on this depends the method taken to clarify many vegetable juices.

It is found in many plants; in nuts, grains, apples, grapes, and fruit of all kinds; in flowers, young shoots of trees, green leaves, &c. It abounds in the juice of the Papau-tree; when this juice is boiled, the albumen falls down in a coagulated state; it is likewise met with abundantly in mushrooms and in different species of fungi. The principal part of the almond, and of the kernels of many other nuts, appears, from the experiment of Prout, to be a substance analogous to coagulated albumen. The juice of the fruit of the Ochra (*Hibiscus esculentus*) contains a liquid albumen in such quantities, that it is employed in Dominica as a substitute for the whites of eggs in clarifying the juice of the sugar-cane. Like gluten, it soon putrefies, particularly when kept moist, or in stagnant water. It is contained under the fibrous rind of flax and hemp, and its decomposition during steeping occasions the ready separation of the fibres, and likewise the unwholesome and offensive odour of water in which this has taken place. It is this also which occasions the disagreeable and unhealthy smell of decaying leaves of vegetables, and particularly of cabbages, and of the water in which they have been boiled. Like animal albumen, it consists of carbon, oxygen, hydrogen, and nitrogen.

2286. *Yeast, or the vegetable ferment,* which we shall see more of under "Fermentation," is supposed to be either gluten or vegetable albumen; but it does not appear to be absolutely certain whether it is one, or modification of both.

2287. *Vegetable fibrin and vegetable casein* are enumerated among the proximate principles of vegetables by some late writers; but as it does not appear certain that they are not identical with those already known and described, we avoid rendering our subject unnecessarily complicated.

SECT. V.—SUGAR, OR THE SACCHARINE PRINCIPLE.

2288. *Sugar is very generally diffused through the vegetable kingdom;* but its importance demands that it should be treated of at large in a separate part of this work. At present it is proposed to consider it only in brief as one of the proximate principles of vegetables. Sugar exists more or less in almost all vegetables, but abundantly in ripe fruits, and the roots of the beet, carrot, &c. It is procured most plentifully, as is well known, from the juice of the sugar-cane and of the maple-tree.

2289. *There are several species of sugar* which agree in having a sweet taste, but which differ in other respects. 1. *Cane-sugar*, or common sugar, which is seen in its purest state when crystallized in white sugar-candy, and in refined sugar. Sugar from the maple-tree and beet root is the same as that from the cane. 2. *Sugar from grapes* contains less carbon than cane-sugar, and is not so sweet; it requires two and a half times as much of this sugar to sweeten to the same degree as cane-sugar; it cannot be made to crystallize distinctly, but solidifies in grains; it dissolves less rapidly than cane-sugar, and gives a more fluid sirup. Sugar of malt agrees with this, and also the sugar of honey, of raisins, figs, and many other sweet fruits. There are other varieties of sugar from various vegetables, but as they are not well understood, and not important, we need not mention them.

2290. *We have already stated that sugar can be prepared from starch;* and hence the reader may be less surprised at being informed that the woody fibre, or the wood of vegetables, a principle which will be described, has been employed for the same purpose. Persons not familiarized with chemistry may, perhaps, consider it as a piece of pleasantry to be told that sugar has been made from common wood, deal boards, sawdust, straw, and even linen rags, all of which consist of woody fibre; yet this has been effected by Braconnot through the action of sulphuric acid; but as the fact is rather illustrative of the powers of chemistry, and the nature of vegetable substances, than applicable at present to any practical purpose, we shall not enter into farther details respecting it.

2291. *The only sugar in general use in Britain* is that of the sugar-cane made in the West and East Indies; the maple-tree sugar is made and used in North America, and the beet root sugar in France. Besides the use of sugar for domestic purposes, it is extensively employed for producing ardent spirit, either pure, or in wine, beer, and all fermented liquors; and it is the only substance from which this can be procured, as will be fully explained under "Fermentation," "Brewing," "Wine-making," and "Distilling." It is likewise employed in the preservation of fruits.

There are various opinions respecting the nutritive properties of sugar. It is readily digested by the healthy stomach; but with some dyspeptic individuals it does not agree.

Sect. VI.—mucilage.

2292. *It is usual to consider mucilage and a solution of gum in water as the same;* but Hermstadt makes this distinction: the solution of gum in water is transparent and glutinous, and can be drawn out into threads, whereas that of mucilage is opaque, does not feel glutinous, but slippery, and cannot be drawn into threads. Dr. Bostock also takes a similar view of the subject. Of mucilages there are a great variety of kinds existing in the roots, stems, leaves, and seeds of many plants. They seldom or never separate spontaneously, but may be obtained artificially in a state of tolerable purity, though it is impossible to separate them completely from starch, gluten, sugar, &c. Only a few species have been examined, and we are uncertain how far their properties agree. Linseed yields one of the purest, which is well known in what is called linseed tea; when thick, it much resembles solution of gum Arabic. Mucilage is perfectly soluble in cold and hot water, and is easily extracted by boiling, as from the roots of marshmallows, the kernels of quinces, and most bulbous roots and fleshy leaves. Many of the fuci also yield a large quantity; some lichens have so much, that they have been used for the purpose of gum in calico printing. Mucilage is found more or less in barley, wheat, and all the grains used for brewing and baking.

Sect. VII.—gum.

2293. *Some trees suffer their gum to transude* either spontaneously or by incisions made in them; it becomes concrete by drying in the air. All gums are easily dissolved in water, and are then nearly analogous to mucilage; but they do not dissolve in spirits of wine nor in oils. They readily unite with sugar, and their composition is so analogous to it, that they are easily converted into that substance by a chemical process, which, however, is not employed, because sugar is procured more economically in another way. The uses of gum are well known. The principal gums among us are:

2294. *Gum Arabic*, the most valuable kind, which exudes from different species of mimosa, particularly the *vera*, a native of Arabia. The best is colourless, and very transparent.

2295. *Gum Senegal* does not differ much from the last, but comes to us in large pieces, and is much employed by the calico printers. It is the produce of the Acacia *Senegalensis*.

2296. *Gum tragacanth* is very different from the gums already mentioned, and is the produce of the *Astragalus tragacantha*, a thorny shrub growing in Syria and the islands in the Levant. It does not dissolve in cold water, but swells up into a mucilaginous mass. and requires digesting in hot water.

2297. *Cherry gum* is more analogous to gum tragacanth than to gum Arabic, as it dissolves in hot water, but not in cold. It exudes from the *Prunus avicum*, or black cherry-tree of this country; also from the plum, peach, and apricot-trees.

The gums are seldom employed as food, and, it is said, are not very nutritious, though the Africans in Senegal sometimes subsist upon it during the gum harvest.

SECT. VIII.—LIGNIN, OR WOODY FIBRE.

2298. *This name has been given to the solid skeleton, as it may be called, of plants,* or what remains after all the principles which have been just described are separated. This skeleton is composed of an infinite number of extremely minute fibres, which are arranged in bundles; so as to constitute the various forms of stems, branches, and leaves; and these, together with the cellular or pithy part between them, make up the solid through which the juices flow. Every one has seen leaves, in the autumn and beginning of winter, decayed, so as to have only the veins or fibres remaining: this is the lignin, or wood, of the leaves.

2299. *The properties of lignin may be examined* by boiling some wood rasped, or sawdust, for a long time in water, to carry away such substances as are soluble in this fluid, and then treating it with alcohol, to dissolve the resinous principles. After this, nothing would be found to remain but a fibrous substance, without taste or odour, and which would undergo no change by keeping in the dry: this would be pure lignin, and would amount to about 96 per cent. in most kinds of wood.

2300. *The ligneous part, or lignin, of esculent vegetables is in far less proportion than in wood; yet it is never absent,* since it is necessary to form the skeleton of the plant. It is seen in the stringy part of culinary vegetables, as in many parts of the cabbage; but is most striking in the hemp and flax plants, their long fibres consisting of this very woody matter arranged round the external part of the stem.

2301. *Lignin is itself composed of* the same elements as all the other proximate principles consist of; in 100 parts there are 51·43 of carbon, 42·73 of oxygen, and 5·82 of hydrogen; and when it is burned, the oxygen, hydrogen, and part of the carbon fly off, leaving only remaining the carbonaceous part of the skeleton, in the form of charcoal.

Wood, under ordinary circumstances, as is well known, is indigestible, and unfit for food; those vegetables which have much of it in their structure are improper; and it is only the most succulent, that is, those which have much juice, or other nutritious principles, in proportion to their woody fibre, that are employed; yet the substance we are now considering is (as we have already hinted) not entirely incapable of being employed for human sustenance.

2302. We shall see under the article "Bread," in Book IX., Chap. III., that wood itself can be used in various ways to assist in increasing the quantity of nutriment; and chemistry has opened a new view of the subject, which may, perhaps, some day, extend the bounds of the vegetable kingdom to the support of life. We mention these discoveries, because, although they are not applied at present in practice, yet they are intimately connected with the subject of aliment, and the view which we are attempting to give would be altogether incomplete without noticing them.

2303. *The discoveries to which we allude were made by M. Braconnot,* a French chemist, and are described at length in Vol. XII. of the *Annales de Chimie.* If the sawdust of hard wood be mixed up with strong sulphuric acid, it will be dissolved: when the mixture has got clear, add chalk to saturate the acid; then strain off the liquor from the insoluble sulphate of lime, and boil it down to dryness. A substance will now be found in the bottom of the vessel very much like gum Arabic, and which is the produce of the sulphuric acid acting upon the lignin, or dry indigestible fibre of the wood. This substance, indeed, appears to have all the properties of gum; it is transparent and yellow, shining like gum, dissolves in water, making a viscid, adhesive paste that will join bodies together. Gum is known to be to a certain degree nutritious; and here is a new substance possessing similar properties. But this is not all. If this gum be once more treated with sulphuric acid, by mixing and heating them together, the gum is converted into sugar capable of being granulated, and which, though not of the same strength as cane sugar, would serve for the purpose of distillation, and many others. To say that these processes would be too expensive to be applied at present to any practical use is trifling; and we envy not the person who could urge the objection with a view to lessen the interest which such discoveries must excite. In the progress which mankind has been making from the rudest state, facts themselves have been first ascertained: their application has been a second step, and often very gradual and slow. But it is quite unnecessary to enlarge upon this subject: the history of inventions, and the advancement of society, present innumerable proofs of the most striking kind, that discoveries are not to be undervalued because we cannot see their immediate bearing; and if even nothing farther shall be accomplished, yet the beautiful simplicity of vegetable nature flashes at once upon the understanding, and this knowledge seems to give man a power hitherto unknown and unsuspected.

2304. *It now appears that starch, gum, sugar, lignin, and probably other vegetable principles, are so nearly allied in their composition* (as we have already pointed out), that little is necessary to cause one to assume the form and properties of the other. But here we must make a distinction, and draw the line between the feeble powers of human chemistry and those extraordinary, but altogether incomprehensible, powers which belong to the chemistry of nature.

2305. *Starch is not merely a substance consisting of definite elements, but it is a substance having an organic structure:* it consists of minute vesicles, of oval forms, that can be seen only by a good microscope: now, though we can convert these into the substance called sugar, yet the chemist cannot bring this sugar back again to starch; though he can make sugar from starch, he cannot make starch from sugar; he cannot organize. In like manner is lignin, a most extraordinary organized substance, composed of bundles of tubes fifty times finer than a hair, the finer fibre of flax being a bundle; now lignin can be made, as we have seen, into sugar, but the latter substance cannot be brought back to the state of those minute woody fibres. We know from chemistry the composition of all those substances: we know that they all consist of carbon, oxygen, and hydrogen; elements which we can procure from mineral bodies; yet, though we have these elementary bodies in abundance, we cannot out of them compose the simplest organic body. The work of organization is altogether beyond the comprehension of the human mind.

2306. *Now it is a fact which we learn from extensive observation,* that, in order that matter shall be fitted for the food of animals of any kind, it should be prepared by having first passed through the vegetable kingdom; and that it should there have been employed in forming vegetable structures; in short, it must have been what we term an *organized* body, or a body possessed of a certain species of life, and constructed in a peculiar manner very different from mineral substances. No animal can subsist upon mineral bodies, even though they should contain nearly the same elementary principles as vegetables: these elements must have been first organized before they can constitute food for an animal. Vegetables can extract food from mineral substances, and prepare it for animals, by first converting it into their substance; after this, the same matter may be introduced into the animal system, and undergo such farther modification as to be *animalized;* it now passes into the animal kingdom, and is capable of affording sustenance to this higher class of beings. Here, then, is a part of that beautiful order and gradation which we discover in every part of creation. This chief use of vegetable life, that of conducting to a higher order, may seem to be contradicted by animals feeding upon each other; but, on closer examination, it will be found that this exception is more apparent than real, as we may observe that carnivorous animals live upon those that feed upon vegetables, so that still we trace that the entrance of matter into the living system is through the vegetable kingdom.

2307. *A bar seems, therefore, opposed to the extent of our chemical power;* we cannot by its means increase the quantity of organized matter; but it is evident that human knowledge and art have already wonderfully modified the nature of organized matter, so as to render available as food much that in its natural state was unfit; of which the arts of agriculture and of cooking furnish eminent examples.

2308. *In prosecuting these researches, Braconnot was desirous of trying how far* the changes from lignin to sugar could be effected, and whether every condition of this principle could be so converted. For this purpose he tried, not only sawdust, but, with equal success, hemp, straw, and even linen rags and paper, all of which consist of lignin, and all of which he converted into sugar.

2309. *But it is now many years since that Professor Auchtenrieth of Tubingen showed* that, by proper management, lignin might be converted into a species of bread (Prout, *Phil. Trans.*, 1827. See receipt in Chap. III., Book IX., "On Bread"). "This discovery," Sir John Herschel observes, "which renders famine next to impossible, deserves a higher degree of celebrity than it has obtained." And lest it might be supposed, in what we have said above, that there is a certain dash of the extravagant, we shall beg leave to quote a few farther remarks from the authority we have just cited, whose practical as well as enlarged views no one will dispute. "The transformations of chemistry, by which we are enabled to convert the most apparently useless materials into important objects in the arts, are opening up to us every day sources of wealth and convenience of which former ages had no idea, and which have been pure gifts of science to man. Every department of art has felt their influence, and new instances are continually starting forth of the unlimited resources which this wonderful science developes in the most steril parts of nature. Who, for instance, would have conceived that linen rags were capable of producing *more than their own weight* of sugar by the simple agency of one of the cheapest and most abundant acids; that dry bones could be a magazine of nutriment capable of preservation for years, and ready to yield up their sustenance in the form best adapted to the support of life, on the application of that powerful agent steam, which enters so largely into all our processes, or of an acid at once cheap and durable; thus, sawdust itself is susceptible of conversion into a substance bearing no remote analogy to bread, and though less palatable than that of flour, yet no way disagreeable, and both wholesome and digestible, as well as highly nutritive?"

Notwithstanding these announcements, however, it is but just to add, that some persons think it possible that the apparently nutritive properties of lignin, as treated by Professor Auchtenrieth, might have been partly owing to some starch which generally accompanies the woody fibre; and we have said so much, rather to show the power of chemistry as applied to our subject, than as anything of great practical advantage.

Sect IX.—Vegetable Jelly.

2310. Several vegetables, but particularly ripe fruits, as currants and gooseberries, yield a juice by pressure, which, when carefully evaporated at a temperature of 200°, the concentrated portion of it concretes into a tremulous gelatinous mass, quite distinct from animal gelatin, and from gluten, as it contains no nitrogen. This substance is well known by the name of *jelly.* It is scarcely soluble in cold water, but very soluble in hot water, and when cold, again coagulates into the form of jelly. When long boiled, it loses the property of gelatinizing by cooling, and becomes analogous to mucilage. This is the reason that, in making currant, or any other vegetable jelly, when the quantity of sugar added is not sufficient to absorb all the watery parts of the fruit, and, consequently, it is necessary to concentrate the liquor by long boiling, the mixture often loses the property of gelatinizing, and the jelly, of course, is spoiled. Vegetable jelly exists more or less in all ripe acid fruits, as the orange, lemon, gooseberry, &c. It is considered very analogous to gum with vegetable acid.

To procure the jelly free from the acid, if the jelly which has gelatinized be put into a sieve, the acid gradually filters through, and, by washing with water, may be separated, leaving the jelly pure; this will dry into a hard mass, not very different from gum. Braconnot, who first observed this fact, proposes the name of *pectin* for the substance.

SECT. X.—VEGETABLE OILS.

2311. *Oil is distinguished by its peculiar unctuous feel, by its inflammability, and refusing to mix with water.* Animal oil has been described as "Fat," Chap. II., Book VII. The vegetable oils are divided into fixed and volatile. They are called *fixed* when the greasy stain which they give to paper does not disappear on the application of heat, and when they do not rise in distillation at the temperature of boiling water. *Volatile* oils are those whose stain on paper disappears with a gentle heat, and which, when distilled with water, rise at the temperature of 212°. The fixed vegetable oils form a numerous and important class.

2212. *Fixed Vegetable Oils.*—These exist ready formed, and uncombined with any other substance, in the kernels of many seeds. They are also found in the roots, bark, and wood; but there they are intimately combined with other principles of the plants. These are usually procured from the seeds and kernels of plants by pressure; hence they are often called *expressed* oils. The substances are put into bags of hemp or hair cloth, and subjected to the action of pressing-mills, at first without heat; what is expressed first is the purest oil, and is called *cold drawn;* afterward some heat is applied, by which a second quantity is obtained of an inferior kind. By this process some mucilage is pressed out together with the oil; and as this deteriorates the quality of the oil, it is afterward, but with some difficulty, separated, and the oil is said to be purified. Fixed oils, when perfectly pure, are quite transparent, either colourless, or of a pale yellowish or greenish tinge, and without smell or taste; when they possess these in their ordinary state, it is owing to the mucilage and other matters mingled with them. They are usually fluid, but of thickish consistence, and they congeal at moderately low temperatures; some are naturally concrete. They combine readily with alkali, forming soaps.

Fixed oils do not boil by being converted into vapour until they are heated to 600°. When a sufficient heat is applied, and vapour is formed and then condensed, the condensed oil is found to have had its properties altered: it has become more limpid and volatile, having lost some of its carbon. When expressed oils are exposed to a warm atmosphere, they gradually acquire a sharp taste and smell, and become thick. This change is termed *rancidity*, and is owing to their absorbing oxygen.

2313. Fixed vegetable oils are subdivided into *fat* and *drying* oils.

2314. *Fat vegetable oils* are those which will not dry or become hard of themselves when spread on any substance, but remain always liquid, or soft and greasy, in the ordinary temperature of our climate. Fat oils, in general, will not unite with water alone; yet, by the addition of mucilage or sugar, they mix with it by agitation, and such mixtures are called *emulsions*. These oils require to be heated to 600° before they boil, and do not inflame until their temperature is elevated to this point. When exposed to the air, they become more viscid, and acquire a degree of rancidity; but when fresh, they have little or no smell; they are never perfectly transparent, but have always a slight yellowish or greenish tinge. The principal fat vegetable oils in use with us as food are olive oil, rape-seed oil, and almond oil: others, employed by us only for procuring light, as palm oil and cocoanut oil, have been described in Chap. II., Book IV., "On Artificial Illumination."

2315. *Olive oil* is so useful in domestic economy as to demand more attention. The description of the olive, from the pulpy part of which it is obtained, will be given in Chapter IX., on "Fruits." Olive oil is brought to us from Italy, Spain, and the Ionian Islands, but chiefly from the first of these countries. The best oil known in our markets is made in Florence and Lucca, and comes from Leghorn; but most of our olive oil is Neapolitan, produced in the provinces of Puglia and Calabria Ultra, and called *Galipoli oil*, from the place whence it is exported. A great deal is used by the wool manufacturers. It is produced in the following manner:

The oil is contained in the pulpy outside of the fruit, whereas most other fruits have their oil in the nuts or kernels. The olives are gathered ripe in November, and immediately bruised in a mill, the stones of which are set wide enough not to crush the kernel; the pulp is then subjected to the press in bags made of rushes. By the first gentle pressure the best, or *virgin* oil, is obtained; and by increasing the pressure so as to break the kernels, at the same time moistening the residuum with water, and applying sometimes a slight degree of heat, a second quality is procured, which, though mixed with the water, on being suffered to remain undisturbed, soon separates, and, although inferior to the first, is still fit for the table. Sometimes a third quality is produced by boiling the pressed cakes in water, and skimming off the oil; this is used by the soap-boiler and other manufacturers. Much depends, not only on the quality of the fruit, but also on its being exactly in the proper degree of maturity; if not sufficiently ripe, the oil has a bitterish taste; if too ripe, the oil is fatty. After the oil has been expressed, it is necessary that it be separated from the mucilaginous matter that accompanies it. For this purpose it is suffered to rest till the mucilage and impurities subside, and the oil is found upon the top. If it be immediately put carefully into clean glass flasks, and secured from the air, it undergoes no farther change. The common oil put into casks cannot be preserved above a year and a half or two years. The oil used for the table is sometimes adulterated with poppy oil. This fraud may be detected by exposing the oil to a freezing cold: the olive oil will congeal, while that of poppies will remain fluid. But a contamination of a pernicious kind by lead is said to occur from its having been kept in leaden cisterns, either in Spain, where this is practised, or in this country. Good olive oil should be inodorous, insipid, soft, and agreeable in the mouth. Its analysis, according to Gay Lussac and Thenard, is, in 100, carbon, 77·21; hydrogen, 13·3; oxygen, 9·4.

2316. *Rape-seed oil* is extracted from the *Brassica napus* and *campestris.* It is made chiefly in Flanders, where it is used for the table, and is said to be employed for adulterating olive oil; but though very pleasant when quite fresh, it is liable to become rancid.

2317. *Almond Oil.*—This oil being united to much albuminous and mucilaginous matter, easily mixes with water, and forms emulsions, for which purpose it is much employed in pharmacy. The oil is obtained by expression from the fruit of the almond-tree (*Amygdalus communis*). When pure, it is perfectly inodorous, and of an agreeable taste.

2318. *Castor oil,* obtained from the seed of *Ricinus communis*, or *Palma Christi,* is used only medicinally.

2319. *Many fixed vegetable oils do not remain liquid in our ordinary temperatures;* some of them are called *vegetable butters.* These are very numerous; but the principal ones known to us are *palm oil,* from the palm; *cocoanut oil,* from the kernels of the cocoanut; *butter of cacao,* procured from the kernels of the *Theobroma cacao*, or chocolate nut. These oils, which are solid with us, but always soft or liquid in warm climates, are employed in India and Africa as substitutes for butter in cooking, and also for making candles. See Book IV., "On Artificial Illumination."

2320. *Drying oils,* when exposed to the air, acquire a pellicle on the surface; and if they are spread in a very thin layer, they harden and become solid, resembling resinous bodies, from the absorption of oxygen: on which account they are employed to mix with colours in painting, which the fat oils will not serve for, on account of their not drying. The principal drying oils are linseed oil, poppy oil, nut oil, hempseed oil.

2321. *Linseed oil,* from the seeds of the flax plant (*Linum usitatissimum* and *perenne*). The seeds are generally roasted before the oil is expressed, for the purpose of drying up the mucilage; it is only used in oil painting and in varnishing.

2322. *Poppy oil,* extracted from the seeds of *Papaver somniferum*, is much cultivated in France, Holland, and Germany for this purpose. It is clear and transparent, and dries readily; it is therefore employed in painting; when pure, it is without taste or odour. It is occasionally also used for the same purposes as olive oil, having none of the narcotic qualities of the poppy.

2323. *Hempseed oil,* made from the seed of the hemp (*Cannabis sativa*), is sometimes employed in painting; but in Russia it is extensively used as food, though its taste is harsh and disagreeable.

2324. *Nut oil,* from the fruit of *Corylus avelana*, is used in this country only for painting; but in the middle departments of France it is employed as a seasoning for food; it is apt to become rancid.

2325. *The drying quality of these oils is increased by boiling,* before which they are said to be *raw.* The method of boiling for this purpose has been described in Book I., under "House Painting."

2326. *Resins and natural balsams are dissolved by fat oils,* with the assistance of heat; and these oils, united to the fixed alkalies, make *soap,* an article of such importance as to demand a separate description in a subsequent part of this work. See Book XXII.

2327. *Volatile oils,* called also *essential oils,* are obtained from various parts of aromatic plants, as the flowers, leaves, bark, wood, and roots, rarely from the seeds, which mostly contain fixed oils. When these oils exist in the plants in great abundance, and are contained in cells near the surface, they are sometimes procured by simple expression, as is the case with the oil which lies in the rind of oranges and lemons; but the greatest number are procured by distillation as they rise, or are converted into vapour at the same heat as water, 212° ; hence their name *volatile;* for, as we stated, the fixed oils require 600° to make them volatilize or change into vapour. The parts of the plant containing the volatile oil are put into a still with a quantity of water, and a moderate heat is applied. The oil is separated, rises with the aqueous vapour, and is condensed with it. Most of these oils, being lighter than water, swim upon the top; a few are heavier, and sink to the bottom. The volatile oils have not the unctuous quality of the fixed oils, but are generally as liquid as water, though a few are somewhat viscid. They have an acrid and burning taste, and an odour extremely powerful, often very fragrant; the delightful odour of flowers proceeds from the evaporation of the essential oils, which are formed and are contained in their cells.

They are soluble in strong alcohol, and hence the *essences* of perfumers; but, on adding water to the solution, they are precipitated. They unite with water in a small quantity, which takes place in the above-mentioned process of distilling them; and this union constitutes the distilled waters of pharmacy. From their great volatility, and having no fatty qualities, the stain which they make on paper when dropped upon it disappears altogether when held near the fire, if the oil has been quite pure: if a greasy spot remain, it has been mixed with fixed oil.

They do not unite readily with alkalies, like the fixed oils, forming a species of soapy compound called by the French *savonules.* When exposed to the air, they thicken from the absorption of oxygen. The most abundant and useful of the essential oils is the oil of turpentine, obtained by distillation from the natural juice, in which it is combined with resin in the fir tribe. Most of these oils are employed in pharmacy or as perfumes. Among the latter are the essence of jasmine, violets, roses, bergamot, &c. (See farther, "On Distilled Waters and Oils," Chap. III., Book XX.) Oil of turpentine has been described in Book I., among the materials for painting.

SECT. XI.—VEGETABLE WAX.

2328. *A species of wax is a product of the vegetable kingdom,* and may be extracted in considerable quantities from various plants. The varnish which appears upon the surface of many leaves consists of this substance, and it is found also in the pollen of flowers, from which, and its analogy to the honeycomb, it has been supposed that the bees only collect their wax from the vegetable kingdom; but it has been shown by Opperman (*Ann. de Chim.*, xlix., 240) that animal and vegetable wax differ somewhat in their constituents; and Huber found that bees made wax when fed upon sugar only. Hunter also pointed out that the substance which the bees procure from the pollen is not wax, but a substance which they gather for the bee-maggots, and called *bee-bread.* Bees' wax, therefore, is an animal substance secreted from the organs of the bee, as has been mentioned under "Artificial Illumination."

2329. *Vegetable wax may be regarded as a fat oil,* having become concrete by the absorption of oxygen in a natural state: accordingly, we find in different vegetables various degrees between oil and solid wax, which constitute the vegetable *butters,* as the butter of cacao; when they become more solid, they are called vegetable *tallow,* as the tallow of croton; when it is very solid, it takes the name of wax, as the *myrtle wax* of America, extracted from the seeds of *Myrica cerifera,* and the *pela* of the Chinese.

The varieties of vegetable wax employed in artificial illumination have been already described in Chap. II., Book IV.

SECT. XII.—RESIN.

2330. *Resins are solid substances of vegetable origin,* highly inflammable, giving much soot by combustion; insoluble in water, but soluble in essential oils and in alcohol. They are supposed to be volatile oil saturated with oxygen, in the same manner as wax is thought to be fixed oil with oxygen. They often exude spontaneously from trees, sometimes from their artificial wounds, and are generally, at first, combined with volatile oil, from which they may be separated by distillation. Common resins may furnish a good example of this. Every one has seen a yellow, transparent, highly viscous substance, called *turpentine,* occasionally exuding from deal or fir. This substance consists of the essential oil of turpentine holding in solution common resin. Large quantities of this are produced from the *Pinus sylvestris,* or Scotch fir, in the north of Europe, where there are vast forests of it; and by distillation the common oil of turpentine (improperly called spirit) is drawn off, leaving behind masses of the yellow resin in the solid state. *Venice turpentine* is procured from the larch (*Pinus larix*). *Tar* and *pitch* are also made from the pine and fir tribe; but to form tar, the logs of wood are cut down and exposed to a strong heat in tar-furnaces, by which the turpentine is partly decomposed and converted into an empyreumatic pitchy oil, called tar; and the latter, when inspissated by boiling it, pitch. The term gum is improperly applied to many substances which are resins, as gum mastic, gum sandarach, gum copal, &c. Gums are soluble in water, while these substances are not, but only in spirits of wine.

2331. *Gum resins* are substances intermediate between gums and resins. If they be digested in water, the gum dissolves and leaves the resin; and when they are digested in spirits of wine, the resin dissolves and leaves the gum. If they are digested in a mixture of alcohol and water, great part of both resin and gum is dissolved. Under gum resins are comprehended aloes, asafœtida, gamboge, myrrh, guaiacum, &c.

2332. *Balsams* are both fluid and solid. They consist of resin, volatile oil, and benzoic acid, without the last of which they are not balsams. The terms *Canada balsam* and *copaiva balsam* are improper and obsolete, these substances not being balsams. *Benzoin, tolu, Peruvian balsams,* are real balsams.

Sect. XIII.—Camphor.

2333. *Camphor appears to possess* some of the properties of a concrete volatile oil; but it is a matter quite distinct from all other bodies. It is solid, white, and transparent; friable, but not easily pulverized; has a peculiar penetrating fragrant odour, and a bitterish acrid taste, followed by a sensation of coldness in the palate. It is extremely volatile and combustible, giving out much smoke, swims on water, and is scarcely dissolved by it, though it is easily by alcohol.

Camphor exists in a greater or less quantity in the roots, branches, and leaves of many plants, particularly in the essential oils, as the oils of rosemary, marjoram, sage, and lavender. But what is brought to this country, and used in medicine, is procured by distillation from the roots and smaller branches of the *Laurus camphora* and *Sumatrensis*. From its volatility, it is soon dissipated when exposed to the air; and if enclosed in a glass vessel, its vapour crystallizes on the inside. When thus diffused through the air, it acts as a poison to many insects; hence its use in defending clothes from moths. It is poisonous to all animals taken into the stomach in large quantities, although, like many other poisons, it is useful in very small quantities when employed medicinally.

Sect. XIV.—Tannin, or Tannic Acid.

2334. *Tannic acid has been frequently named the astringent principle*, and is very abundant in the barks of trees, and in all plants that are of an astringent nature. It exists abundantly in the bark of oak, and in large quantity in the excrescences called gall-nuts on several species of oak. It is found also plentifully in tea, sumach, and whortleberries; but in these it is always associated with gallic acid: in catechu and cinchona bark it exists in the greatest abundance, and without gallic acid. When tannic acid is prepared quite pure, it is highly astringent, and soluble both in water and alcohol. It is white, and without odour, but on exposure to air it becomes brown, as it is generally seen. Though it is itself soluble in water and alcohol, it has the useful property of forming with gelatin a compound not soluble in water; in fact, rendering gelatin, which is a very soluble substance, insoluble; hence the use of bark in making leather.

2335. *To make leather*, skins, which consist almost entirely of gelatin, are steeped in the tan-pit with a quantity of bark, chiefly of the oak; they thus become converted, by combination with the tannin, into a substance insoluble in water, and this, after going through certain operations, constitutes that useful material, leather, which is no longer liable to putrescence. A great deal of tannic acid exists also in red port and in coffee. Dr. Thomson is of opinion that tannic acid, like most other vegetable substances, is susceptible of different modifications, and that what is procured from different plants is not exactly of the same quality independently of the quantity. 100 parts of tannic acid are composed of carbon, 52·69; oxygen, 43·45; and hydrogen, 3·86. By some it is arranged among the vegetable acids.

Sect. XV.—Colouring Matter.

2336. Peculiar substances exist in vegetables called colouring matter; but this rarely or never occurs in an insulated state, being always attached to some other proximate principle, such as mucilaginous, resinous, or other substances, by which their solubility is affected. For these, see Chap. XI., Book XVII., "Dyeing."

Sect. XVI.—Vegetable Acids.

2337. *Acids form a class of substances having peculiar properties. They are sour to the taste, and they change vegetable blues to red.* The latter property is the surest and most delicate test, for it may happen that an acid may be diluted so much with water that its sourness is not sensible to the taste; but if a little of the decoction of red cabbage, which is blue, be dropped into it, the colour will instantly be changed to red: or, if pieces of paper died with vegetable blue be dipped into a liquid supposed to contain an acid, the same change will be effected. Paper coloured blue by litmus is kept by chemists for this purpose, under the name of *litmus test paper*.

2338. *Another property possessed by acids is*, that when they are united to an alkali, salts are formed that are neither acid nor alkaline, and hence called *neutral salts*. The acid and alkali in this case are said to *neutralize* each other.

2339. Of acids, some are formed by chemical action among mineral bodies, as nitric acid, sulphuric acid, &c.; these are called *mineral acids;* but at present we propose considering only such of the vegetable acids as exist ready formed in plants, and which enter into the composition of materials employed as food.

2340. The researches of modern chemistry of late have greatly added to the number of vegetable acids; but some are extremely rare, and could only find a place in a system of chemistry which should contain an account of every known substance. The following are the principal vegetable acids: acetic acid, malic acid, citric acid, tartaric acid, oxalic acid, and gallic acid.

2341. *Acetic acid* exists ready formed in the juices of many plants, either in a separate or free state, or combined with lime or potash, forming salts. It is an abundant product of the acetous fermentation, and it is also formed by the destructive distillation of vegetables, as in the case of wood vinegar. Common vinegar is an impure acetic acid; but this being an article of great importance, it will be treated of at large in another part of this work. See Chap. VI., Book VII.

2342. *Malic Acid.*—This acid derives its name from the apple, in which it abounds, particularly before they are ripe: it is likewise found in many other fruits, together with other vegetable acids, and is almost the only one in the service-tree (*Sorbus aucuparia*), from which it is sometimes called the *sorbic acid.* When pure it is exceedingly sour.

2343. *Citric Acid.*—This acid exists naturally in many acidulous fruits, but in the greatest quantity in the juice of the lime and lemon, from which it is now obtained pure in a crystallized state. The crystals are transparent; if kept dry, they may be preserved for any length of time, and are sometimes employed as a substitute for lemon-juice.

2344. *Tartaric Acid.*—This exists in several acidulous fruits, particularly the grape and the tamarind, but always combined with lime or potash; and these combinations are neutral salts, called *tartrates* of lime or of potash. The juice of the grape is remarkable for containing abundance of the bitartrate of potash; and during the process of making wine this salt is deposited in the form of a hard crust, and particularly on the sides and bottom of the wooden casks in which the wine is kept to depurate. This substance is called *tartar*, and being impure, and coloured by the wine, it is dissolved and purified; it is then white, and becomes the acidulous substance called *cream of tartar* of the shops. From this the pure *tartaric acid* is prepared by separating the potash from it by a chemical process. When the tartar of the wine-casks is burned to ashes, the tartaric acid is driven off, and the potash remains, which was formerly known under the name of *salt of tartar.*

2345. *Oxalic Acid.*—This acid, so violent a poison in its pure state, abounds in wood sorrel (*Oxalis acetosella*); but it is there combined with a small quantity of potash, and in that case it is not poisonous. When this salt, the oxalate of potash, has been prepared from sorrel, it is sometimes sold, under the improper term of *salt of lemons*, for taking out iron moulds and ink spots, for which purpose it answers equally well.

The resemblance of oxalic acid to Epsom salts has occasioned many fatal mistakes. In cases of poisoning by this substance, the best antidote is chalk or whiting mixed with water, which is preferable to emetics, or potash, soda, or magnesia, which have been also employed. Oxalic acid is easily distinguished by its strongly *acid* taste (and it may be *tasted* without danger), whereas Epsom salts have a *bitter saline* taste.

2346. *Gallic Acid.*—This acid is found in the bark of many trees, and in gall nuts, but always associated with tannin, or tannic acid, already described. It has but a very weakly acid taste, and is astringent and bitter. It is particularly remarkable for striking a deep bluish-black with iron, and from this property it forms the basis of writing ink.

2347. *Prussic Acid.*—This, in modern chemistry, is called the *hydrocyanic acid;* but it is still popularly known by its former name, which was derived from its being a constituent of the pigment Prussian blue. It is one of the most virulent poisons known, a drop or two laid on the tongue being sufficient to occasion death; but, like most poisons, when employed in very minute quantities, it is a useful medicine. It is introduced here only to correct a general opinion respecting it, which now proves to be erroneous, in consequence of the recent discoveries in vegetable chemistry. Although Prussic acid is procured by the distillation of the leaves and kernels of the *Prunus Lauro-cerasus*, or cherry laurel, *peach*, and *bitter almond*, it does not exist, as has been supposed, ready formed in these vegetables. They only contain the ultimate components called *amygdalin* and *emulsin*, from which Prussic acid is formed by their mutual action and that of water during the process of distillation. By this process, a poisonous essential oil, called by chemists *hydruret of benzueli*, is likewise formed from the same ultimate components; and it is to this essential oil, and not to the Prussic acid, that the odour of the peach-blossom is owing. Prussic acid, therefore, being merely the product of a process, cannot be considered as one of the proximate principles of vegetables. See farther, in the description of the "Cherry" and "Peach," Chap. IX., Book VII.

The composition of hydrocyanic acid is very different from acids in general; instead of oxygen, hydrogen is its acidifying principle: it is composed of hydrogen and a gaseous body called *cyanogen*, the latter consisting of nitrogen and oxygen.

Sect. XVII.—VEGETABLE ALKALIES.

2348. *Alkalies constitute a peculiar class of bodies*, which, however, it is difficult to define accurately. They are distinguished by a peculiar *nauseous taste, called alkaline*, and which, as it cannot be described, may be understood by tasting carbonate of soda: they change vegetable blues green, and yellow ones to brown, and they neutralize or destroy the action of acids, and, consequently, restore the blue colour of such vegetable solutions as have been rendered red by them. The most convenient tests for an alkali are slips of paper dyed yellow with turmeric, and sold for the purpose by chemists: if put into any liquid containing *free* alkali, they will be changed to *brown*.

2349. Formerly there were but three alkalies known: soda, called mineral alkali; potash, the vegetable alkali; and ammonia, the volatile alkali: the first two were named, also, *fixed* alkalies. The terms mineral alkali and vegetable alkali, though formerly employed, and constantly met with in old books, and therefore introduced here, are now laid aside as not applicable, since both of them are found in abundance in the mineral and in the vegetable kingdoms. The two *mineral* alkalies, soda and potash, have for their bases peculiar metals, called sodium and potassium; these alkalies are, in fact, oxydes of the metals.

2350. *What are in modern chemistry denominated the vegetable alkalies* are certain substances existing in plants that are possessed of alkaline properties; but they are very different from the fixed alkalies just mentioned, for they do not consist of metallic bases, but are composed of the usual elements of which vegetables are formed. It is interesting to observe that, in all these vegetable alkalies, as has been already noticed, nitrogen is found in considerable proportion, contrary to what is the case in the other proximate principles of the vegetable kingdom.

Soda and potash, though differing altogether from these, being metallic oxydes, occur in abundance in plants; and, although they do not come under the denomination of vegetable alkalies, as the term is now understood by chemists, yet we feel it will be useful to describe them in this place as constituents of vegetables, premising that they must not be confounded with those vegetable alkalies which are not metallic oxydes.

2351. *Soda was called the mineral alkali* because it was originally dug up out of the ground in Africa and other countries; this state of carbonate of soda is called *natron*. But carbonate of soda is likewise procured from the combustion of marine plants, or such as grow on the seashore. *Kelp* is a substance produced by the burning of the fucus or other sea-weeds, and contains much impure soda; it is used in making glass and soap. *Barilla*, a purer kind of the same substance, is made by burning the *Salsola soda*, a plant that grows abundantly at the seaside in Spain. These carbonates of soda, when purified, are much in request by the laundress. (For its use, see Book XXII., "Economy of the Laundry.") Pure carbonate of soda is employed for making effervescing draughts with lemon juice, citric acid, or tartaric acid. Soda, deprived of carbonic acid and every other substance by a chemical process, is called *caustic*, or *pure soda*. Common salt is muriatic acid and soda, or muriate of soda, according to the late nomenclature of chemistry; but at present it is considered to be chloride of sodium, or the elementary principle chlorine united to the metal sodium; consequently, having no oxygen in its composition. It is remarkable that the metal sodium is never met with by itself in nature; having so greedy an attraction for oxygen, that when procured pure by art it falls into the state of an oxyde in a short time; and this oxyde is *caustic potash*.

2352. *Potash was formerly called the vegetable alkali*, because it was obtained from the ashes of land vegetables. When the ashes are mixed with water, the potash is dissolved, and the earths and impurities settle to the bottom. This water is then evaporated by boiling in iron vessels; and the solid substance that remains is the *potash* of commerce, so called from the manner of its production. When this is strongly heated in a furnace, it becomes whiter, and is then *pearlash*. These substances, however, are not the pure alkali or potash; for they are thus united to carbonic acid, being, in fact, *carbonate of potash*. Potash deprived of the carbonic acid by another process is called *caustic* potash, which instantaneously acts upon and corrodes animal substances, and is used by surgeons in their operations. United to carbonic acid in the usual way, it is called *mild* potash, and still preserves somewhat of causticity, as may be observed from its effects upon the skin in washing. Potash, both mild and caustic, is an extremely useful material, being employed in medicine, and for domestic purposes in a great variety of ways, which will be described under their several heads. Potash is also extensively employed in the manufacture of soap, in bleaching, scouring wool, &c. It is principally manufactured in America, Russia, and Poland, where the vast forests furnish an inexhaustible supply of ashes. Small quantities are also made here in country places from the burning of vegetables, particularly fern in mountainous districts; and *wood ashes* of any kind contain potash, to which they owe their detergent quality. *Salt of tartar* has been mentioned as an impure carbonate of potash. See, farther, Book XXII., "Economy of the Laundry."

2353. We will now say something of the most remarkable of those substances to which the term vegetable alkalies is at present restricted.

2354. *Morphia.*—It is well known that certain plants, as opium, possess a principle that induces sleep, called the narcotic principle, and which, if taken in a large quantity, occasions death. This principle has lately been detached from all others, and named Morphia, from Morpheus, the god of sleep. It is now ascertained that morphia, if employed as a medicine in lieu of opium, produces the soothing effects of that drug without the usual feverish excitement, heat, and headache.

2355. *Quinia and Cinchonia.*—These alkaline substances are supposed to contain the febrifuge virtues of Peruvian bark, from which they are extracted. United to sulphuric acid, forming sulphate of quinia and cinchonia, they are considered as more efficacious than the bark itself.

2356. *Strychnia*, a substance extremely poisonous, is extracted from the fruit of the *Nux vomica*, St. Ignatius's bean, and other plants of the genus Strychnos.

2357. *Veratria*, another poisonous substance found in the root of white hellebore (Veratrum album) and meadow saffron (Colchicum autumnale), which last, also, contains colchica.

2358. *Emetia*, a principle extracted from ipecacuanha, and which is the cause of the emetic properties of that root.

2359. *Picrotonia*, the bitter poisonous principle of the Cocculus indicus.

2360. *Solania*, the poison of the woody night shade.

2361. *Cynopia*, procured from the lesser hemlock (Æthusa Cynapium).

2362. *Conia*, from hemlock (Conium *maculatum*).

2363. *Atropia*, from belladonna (Atropa *belladonna*).

2364. *Hyoscyama*, from henbane (Hyoscyamus *niger*).

2365. *Daturia*, from stramonium (Datura *stramonium*).

Sect. XVIII.—Bitter Principle.

2366. It was formerly supposed that there was *one peculiar principle* that occasioned the bitter taste, and which was the same in all plants; but chemists are now of opinion that there is no such determinate principle common to all vegetables; and that the bitter taste proceeds from principles varying, perhaps, in each plant. There are therefore various bitter principles which have different properties. The bitter is intense in quassia, and is called *quassin.* Dr. Thomson thinks it is probable that hops, gentian, and broom contain the same bitter principle. Another called *caffein* is found in coffee. *Scillitin* is the bitter principle of squills. Many varieties of the bitter principle are deadly poisons, as *strychnia*, the bitter of the Nux vomica; *morphia*, of opium. *Nicotin* is a poisonous principle extracted from tobacco. It is important to notice these facts, since very erroneous reasoning has been founded upon the supposition that there was one distinct bitter principle having always the same properties.

Sect. XIX.—A few other Vegetable Principles.

2367. *Extractive Matter.*—In works on chemistry this term has been often employed to express a peculiar supposed principle existing in plants; but Dr. Turner and other chemists observe that it is now doubted whether there be any distinct substance to which the name ought to apply. The term *extract* in pharmacy originally meant any substance extracted by means of some menstruum: and therefore it varied according to the nature of that menstrum; thus, there were *watery extracts* and *spirituous extracts*, since many of the vegetable principles are soluble in water, others, as resins, only soluble in alcohol. From the descriptions given of what has been termed extractive, it appears to be very analogous to some of the bitter principles, which are not yet well understood.

2368. *Caoutchouc.*—This very singular substance, commonly known by the name of Indian rubber, was, not many years ago, used only to rub out black-lead pencil marks; at present, its uses are very extensive, and it will be noticed in various places through this work. (See Index.) It coagulates from the sap of a particular class of tropical trees, from which it flows out by incisions made for the purpose. See, farther, "On Elastic Fabrics," in Chap. VIII., Book XVII.

2369. *Charcoal* is such portion of the lignin as has escaped complete combustion in burning vegetables, and where the carbonaceous part of it alone remains. In this state it admits of no farther spontaneous alteration, and is perfectly incorruptible. It is used for a great variety of purposes. It is an excellent substance for filtering water; it corrects incipient putrefaction in animal substances, and is extensively used as fuel.

2370. *Wood-ashes.*—When vegetables are completely burned in the open air, all the principles above enumerated are volatilized, with the exception of the potash and soda, which have been already described, and which are separated from the ashes that remain. After these alkalies have been extracted, the remainder consists of a small portion of various earths, and even metals, particularly iron, which entered into the organic structure of the vegetables, but which probably were not always essential constituents. Wood-ashes, from the alkali they contain, are often employed for the same purposes as soap.

2371. *Silica*, or the earth of flints, is a substance which one would not expect to meet with as a necessary ingredient in plants, and yet a whole tribe of vegetables has a varnish of siliceous matter on the outside of their stems; the most remarkable of these is the bamboo; the shining polish of this plant proceeds from a thin coating of pure silex, and small concretions of siliceous matter are often formed in the joints of the stems. The greater number of the grasses, and the various species of corn plants, have an external coating of this substance, which nature has the power of dissolving and converting into a varnish. The existence of this flinty epidermis in the stalks of corn is easily shown by the blowpipe, which fuses it into a minute globule of glass. Silica likewise exists in many plants in minute quantities, but in combination with potash, soda, or lime, and appears on their analysis.

2372. *Besides these, several other elementary substances* are found in vegetables on analysis in minute proportion, as phosphorus, sulphur, lime, iron. All vegetables contain a large proportion of water. Indeed, the greater accuracy with which organic matter is now analyzed by experienced chemists, compared with what was the case only a few years back, has very much increased the number of substances that enter into the composition of vegetables in very small quantities, and have, no doubt, their effect in the production of their several properties; but to enter into all the details necessary to exhibit this increased complicacy of constitution would render our work unintelligible to the greater number of our readers, and depart from the simplicity which we are desirous of retaining by confining ourselves to what belongs more particularly to domestic economy. Those who are desirous of following up all the discoveries of modern analysts should consult their late publications.

CHAPTER VIII.

DESCRIPTION OF THE VEGETABLES AND FRUITS USED AS FOOD IN THE BRITISH ISLES.

SECT. I.—INTRODUCTION.

2373. One of the principal advantages resulting to Europe from exploring distant regions has been the introduction of numerous useful vegetables and fruits, which are at present cultivated with much success. Whatever horticulture may have been practised in Britain by the Romans, while they had possession of this island, must have been nearly, if not wholly, lost during the disturbed state of several succeeding centuries; and it is indeed remarkable, surrounded as we are with abundance of every kind of useful fruit and vegetable that our climate will admit of, and which many suppose to be natural to the soil, to find that the introduction of by far the greatest number date no farther back than the reign of Henry VIII.

The edible wild plants indigenous in this island are mostly of small growth and harsh taste; and to the skill of the gardener we owe almost all those which at present form valuable articles of diet.

2374. *In this chapter we propose to give a general description* of all the vegetables and fruits used at present as food in the British isles; but the manner of their production or cultivation will be found in works on Gardening and Agriculture.

2375. *In our arrangement we shall adopt the method* followed by Mr. Loudon in his "Encyclopædia of Gardening," to which we are obliged for many useful facts:

1. The Cabbage tribe; 2. Leguminous vegetables; 3. Esculent roots; 4. Spinaceous plants; 5. Alliaceous plants, or the onion tribe; 6. Asparaginous plants, or the asparagus tribe; 7. Acetaceous plants, or salads; 8. Pot-herbs and garnishings; 9. Sweet herbs; 10. Plants used in tarts, confectionery, and domestic medicine; 11. Plants used as preserves and pickles; 12. Edible indigenous plants not cultivated; 13. Poisonous plants; 14. Edible fungi; 15. Edible marine plants.

SECT. II.—CABBAGE TRIBE.

SUBSECT. 1.—*General Account of the Cabbage Tribe.*

2376. The cabbage tribe belongs to the numerous botanical family of the *Cruciferæ*, or, as Professor Burnett has named them, *Brassicaceæ*, some of which are found as weeds in every field; and to one of them, by means of cultivation, we are indebted for all the varieties at present in use.

2377. *The original wild plant*, called *sea-colewort* (*Brassica oleracea*, Linn.), may be seen growing on the cliffs in various parts of the south coast of England, as at Dover and Penzance; and no one unacquainted with the subject would suspect that it had been the parent of so important and numerous a progeny. It is there seen as a plant of scanty leaves, scarcely weighing altogether half an ounce; and, though it may be eaten, it is salt, and not very tender. It is not supposed, however, that all our cabbages, originating from this wild plant, have been the result of English gardening only. This plant is very liable to run into varieties, and some of these have probably been cultivated in other countries from the earliest times.

2378. *The cabbage was known to the Romans*, and was with them a favourite vegetable. Columella informs us that it was produced in sufficient quantity to be used abundantly as an article of food by all classes of people; and as it was a principle with the Romans to carry the arts of civilization into those countries which they conquered, several fruits and culinary vegetables found their way, through this source, into Germany, Gaul, and Britain. Much, also, is probably due to the earliest monastic institutions. It is not accurately known, however, at what time the cabbage was introduced into this island, but it was supposed to have been cultivated here pretty generally in the times of the Saxon heptarchy, the Saxon term for this vegetable being *kale*, a name by which it is still known in Scotland. The close-hearted variety was for many years brought from Holland, and Ben Jonson speaks of this being the case in his time. It is said that cabbages were first introduced into the north of Scotland by the soldiers of Cromwell, though some refer their being planted there to an earlier date: for a long time they were the only garden vegetable in the northern parts of that country. From the abundance, cheapness, and wholesomeness of this plant, it appears to be the most useful of all the culinary vegetables; and so many are the varieties, that one or other is procurable at every season of the year.

2379. *The cabbage tribe putrefy very quickly*, and in decomposing give out a very offensive odour, owing, it is supposed, to their containing a small portion of nitrogen, in addition to the usual constituents of vegetables. Decayed cabbage leaves should therefore never be suffered to lie about in the vicinity of dwellings, and the water in which this vegetable has been boiled should not be retained on the premises, but be passed off into the drains.

2380. *Cabbages are found in general to be wholesome and nutritive*, and to supply a valuable mixture with animal food; but with some constitutions, particularly those who are dyspeptic, they are occasionally indigestible, and productive of flatulency. Dr. Paris is of opinion that they contain an essential oil which is apt to produce bad effects, and he recommends that they should be boiled in two successive waters till they are soft and digestible. But they may be boiled too much, as well as not enough: in the former case, when soft water is used, much of their nutritive properties are extracted, and are lost in the water.

2381. *The varieties of cabbages* are divided into, 1, the various sorts of Borecoles or Kales; 2, the headed Cabbages; 3, the several kinds of Cauliflowers and Broccoli.

Subsect. 2.—*Borecoles, or Kales* (*Brassica Oleracea*, Linn. Division 1, *Acephala*).

2382. The character of these is to have the leaves loose, and not formed into a close round head, and their leaves are generally curled or wrinkled. They resemble most the original wild plant. They form an excellent vegetable for the table, and being extremely hardy, are considered by many as the best winter greens, and most to be depended upon. They have been particularly recommended for cottage gardens. In an experiment tried to blanch them, they were found to be much improved. They are not in the least injured by frost. There are several varieties of borecole; one variety well known in London, and in almost every garden in Britain, is the *Scotch kale*, which in Scotland is known by the name of *German kale*, or *curlies*, or curly greens.* Some other varieties are more rare, as *Buda* and *Russian kale*. The former is a low and rather delicate plant, which is excellent for the table when blanched: the sprouts are preferable to the heart. It is from the seeds of a variety of kale that the Colza oil, so much used in France for burning in lamps, is procured by expression.

2383. *The Couve Tronchuda* (*Brassica costata*), or Portuguese cabbage, from Tranxuda, Portugal, is much cultivated on the Continent, and was introduced here in 1821; it is grown chiefly for the midribs of the outward large leaves, which, when divested of their green parts, and well boiled, make a good dish, somewhat resembling sea kale. The heart or middle part of the plant is, however, the best for use; it is peculiarly delicate, tender, and agreeably flavoured, without any of the coarseness which often belongs to the cabbage tribe.

2384. *The palm kale, and the true kale, or Cæsarean cow-cabbage*, are both arborescent varieties of brassica; the first growing to the height of ten or twelve feet, and the latter said even to reach to sixteen feet in La Vendée; their stems are simple, and crowned with tufts of leaves, therefore something resembling the palms in part. The heart of the bud is tender and palatable; the outer leaves are given as fodder to cattle, for which purpose the plant is cultivated extensively in Jersey, and the other Anglo-Norman isles.

2385. *Sea kale*, notwithstanding its name, does not belong to this class of plants, but to the asparagus tribe; its description will be found with them.

Subsect. 3.—*Close-headed Cabbages* (*Brassica Oleracea*, Division 2, *Capitata*).

2386. The second division of the brassica consists of those which form their leaves into a round head, as the common white and red cabbage, or into a long head, as the savoys; besides the common white and red, there are several other varieties, as the drum-head, sugar-loaf, &c., and the sub-varieties are brought into use in different seasons, as they are required, some being early, others late.

2387. *The white cabbage is the most common* garden sort. The heads, when well formed, are externally of a yellowish-green colour, and the internal part is very white or blanched; these are from three to twelve, or even fifteen, inches in diameter, and weigh from two to twenty pounds; but the larger varieties are used only for cattle. They are all raised from seeds, are biennials, and are therefore sown the year before it is expected they will have large heads. The first season, while the plants are young, they are often employed as *greens*, under the name of *cabbage plants*, or *cabbage coleworts*; these are pulled up by the roots, and carried to market in that state, which preserves the sap better than when the roots are cut off. Others are transplanted; and when a little farther advanced, when the heads begin to form, they constitute what are called *summer cabbages*. The heads are cut off at various times, according to taste, and the demand for them. In the winter their form is completely round and compact, and they are employed for various purposes, for family use, sea stores, or for cattle. If the ground is wanted, the stalks are pulled up, but sometimes they are left in the ground all the win-

* Some consider another variety, the purple or brown kale, as quite equal, if not superior. The Siberian and the dwarf borecole are also excellent.

ter; and in the next spring fine new shoots proceed from the stems, which are gathered for greens, under the name of *cabbage sprouts*, and which are not inferior to young cabbages. In early cut cabbages these sprouts often form little, tolerably firm heads in the autumn; in the sugar-loaf cabbage particularly, and other forward kinds; these, while young and green, constitute some of the most excellent culinary greens of the season. Gardeners generally suffer a certain number of the strongest cabbage to remain for the purpose of producing sprouts.

2388. *The red cabbage* is of the same general form as the white, but is naturally rather of a purplish colour, mixed with brown, than red. The bluish purple colour, like all vegetable blues, is turned red by any acid; and hence its colour, when employed as a pickle, which is the chief use to which it is applied with us. Its bluish juice is an excellent test for both acids and alkalies; for it turns red with the former, and green by the latter. In Germany they make from this cabbage, as well as from the other varieties, their favourite *sauer kraut;* for the manner of preparing which see Book X., Chap. III., "Pickling." The best kind for pickling is the large red Dutch. The dwarf red, which is more delicate, is principally used for stewing, and is much grown for that purpose on the Continent.

2389. *Savoys* are likewise close-hearted cabbages; but they are distinguished from those already described, by their leaves being very much wrinkled. They are sweeter, and of a more tender texture than the others, particularly the central leaves. They are a winter vegetable, and their season is from November till spring. The dwarf savoy is much improved by frost; and the yellow savoy will bear very severe weather without injury. The green is most tender.

2390. *Brussels Sprouts.*—These are considered as a sub-variety of the last, and are thought by some to be the most agreeable of the cabbage tribe. The stem, particularly in Flanders, is sometimes four feet high; and from the places where the leaves join on sprouts shoot out, which form small green heads, like cabbages in miniature, each being from one to two inches in diameter; the main leaves drop off early. The top of the plant resembles a savoy planted late in the season; it is very delicate in taste, and quite different from the leaves. At Brussels, where they are used as winter greens, they are usually served up at table with a *sauce blanche*, comprised of vinegar, butter, and nutmeg. The tops should be gathered a week or ten days before the sprouts; and the latter, when cooked, should be carefully drained before the sauce is added. The sprouts are best if they have been touched by the frost, resembling in this respect savoys.

2391. *Cauliflower and broccoli* (*Brassica oleracea*, Division *Botrytis*). This division comprehends those which form a head of their stalks and flowers. It was a favourite saying of Dr. Johnson, "Of all the flowers in the garden, I like the cauliflower best." It is, indeed, the most delicate of the brassica tribe.

2392. *It differs from the other varieties* in having its flowers extremely numerous and compact, planted upon a short, thick, succulent stem, and forming a curd-like head that scarcely rises above the leaves. This stem, with the mass of closely-planted flowers, is the part which is cut off and dressed.

2393. *It is not certain at what period the cauliflower was introduced into English horticulture;* but it was cultivated here about the beginning of the seventeenth century, and came to us from the Island of Cyprus. Its cultivation in England has been very successful; and though the Dutch horticulture long excelled the English, yet this vegetable was produced here in greater perfection than in Holland; and, before the French Revolution, used to be exported to that country.

2394. As it requires a richer soil and warmer situation than the other varieties of the brassica tribe, it must always be higher in price; but from the great industry and spirit of our gardeners, it is now become so cheap as to be within the reach of all classes. In 1619, two cauliflowers cost three shillings. The heads of the cauliflowers are not nearly so liable to putrescency after being cut as its leaves, which in this respect are similar to those of the cabbage; and they may be preserved for months through the winter by pulling up the plant entire, picking off the decayed leaves, and hanging them up in a cellar or shed, or by burying them in pits in the ground.

2395. *Broccoli.*—The name is Italian; it is usually considered as a sub-variety of the cauliflower, and is distinguished from it by the head being of a dark green or purplish colour, instead of white, as the latter; though lately gardeners have produced a white broccoli that very much resembles cauliflower in all its valuable qualities. The purple sort, when boiled, becomes green. Broccoli is likewise much hardier, and is made to stand the winter; and it is a great advantage that cauliflower and broccoli bear their heads at different seasons of the year. Both are excellent and wholesome.

Sect. III.—Leguminous vegetables.

2396. *The legumes*, or, as they are also called, *pulse*, contain the greatest quantity of albumen and gluten next to the grains or seeds of the corn plants, and rank the nearest to them in their nutritive qualities. Except the corn plants (which will be treated of under the article "Bread") and the potato, pulse are the most important of the farinaceous esculent vegetables. They consist of the pea, common bean, and kidney bean, lentil, tare, and vetch: the first three only are used as food for man in Britain. Next to fruits and the nut species, perhaps, the pulse tribe were earliest resorted to for nourishment, as it required little labour to prepare it. In their young state, when succulent, several of them form favourite articles on the table; but when they have come to maturity, or are dried, they are less acceptable, requiring strong powers of digestion. It is fortunate, however, that even then they furnish excellent food for various domestic animals; and thus the soil, which would be exhausted by perpetual crops of grain, is enabled to recover its fertility under the less severe production of the various sorts of pulse.

SUBSECT. 1.—*The Common Pea* (*Pisum Sativum*, Linn.).

2397. Of the pea there are many species, but this is the only one cultivated in this country. It has long been known as a culinary vegetable in India, China, and Japan, but is probably not originally a native of a very warm climate. It has no doubt found its way into Britain from the southern parts of Europe, and appears to have been extensively used as one of the staple articles of food in England at a very early period; for it is on record that in 1299, when the English forces were besieging a castle in Lothian, they subsisted upon pease and beans grown in the vicinity, after their provisions were exhausted. The more delicate varieties, however, do not appear to have been known in England until much later, since it was observed by Fuller, in the time of Queen Elizabeth, that pease brought from Holland were "fit dainties for ladies, they came so far, and cost so dear."

2398. *Though culture has produced a great many varieties of pease*, yet they may be all included under two divisions, the white or yellow, and the gray. Of the white, the choicest sorts are raised in gardens, to be eaten green; but vast quantities are likewise cultivated in the fields, and are allowed to ripen to be dried. The gray pease are coarse-flavoured, and are used only as food for horses and cattle.

2399. *The sub-varieties of the common pea are very numerous*, and are continually changing from culture: even the names of them vary, which renders it difficult to determine with respect to the best sorts. Among the principal varieties at present are the *marrow fats*, the *egg*, the *moratto*, the *Prussian blue*, the *rouncival*, &c. Pease form a light, wholesome food when they are green and succulent, and gardeners sow them at various periods, so as to have them fit for gathering in succession. They are generally distinguished into *early* and *late;* the former are often forced on hot beds, and form the grand vegetable luxury at the approach of summer. These, however, are never so rich and saccharine as those which come to maturity by the natural heat of the season; hence green pease are really of the best quality when they are so abundant and cheap that they can be purchased by every one. When the white or yellow sorts are ripened for drying and splitting, they are called *boilers*, as they are mostly used for soup, or pease pudding. Vast quantities of these are consumed in the navy. It is found that, after they have been kept a year, they do not break or fall well in the soup; and this property likewise depends much upon the soil in which they grow. Pease are also ground into flour, which forms a milky solution with water, owing to the presence of an oily matter. Although highly nutritive, ripe pease are much more indigestible than the corns, and the bread they afford is apt to lie heavy on the stomach: it is chiefly confined to the labouring classes, and those who have strong powers of digestion.

2400. When green pease are sent to market in sacks, they are apt to heat, and a fermentation commences in a few hours, by which the pea loses its sweetness and fine flavour; this may be observed constantly in the season in Covent Garden market. Those sent in sieves, or flat, shallow baskets, are not liable to this objection.

2401. *Ripe pease analyzed by Einhoff* gave, in 3000 parts, starch 1265 parts; fibrous matter analogous to starch, with the coats of the pease, 840; mucilage, 249; saccharine matter, 81; albumen, 66; earthy phosphate, 11; volatile matter, 540; loss, 229.

2402. *Sugar Pea.*—This is a variety lately introduced, very sweet, and in which the tough internal film of the pod is wanting. These pods, when young, are boiled whole, and eaten in the manner of French beans.

2403. *The chick pea* is little known in Britain. It is a very small variety, much cultivated in the south of Europe. The seeds do not become soft by boiling; but are sometimes parched in a frying-pan in Egypt and Syria, where they are considered as convenient food for travellers who make long journeys. In Spain, they form an ingredient in the *olla*, a national dish. In Italy, and the south of France, they are sometimes roasted as a substitute for coffee.

Some other small varieties of the pea are known and used in Arabia and India, but they are not of much value, except to the poorest classes.

SUBSECT. 2.—*The Garden Bean* (*Vicia Faba*, Linn.).

2404. *The common or garden bean* has been cultivated in Britain from time immemorial, but is supposed to have been introduced by the Romans, and to have come originally from Asia, whence it spread into Italy, Egypt, and Barbary.

2405. *The seeds* of the large variety of garden bean, called the *Windsor bean*, are preferred for the table. The *Mazagan* is one of the earliest and best flavoured, and the

Green China is late; the seeds of the last remain green when ripe and dried. Other varieties, as the *common horse bean*, the *tick bean*, and the *small Dutch bean*, are cultivated in the fields for fattening domestic animals, for which they are admirably adapted. In some places, meal from beans is mixed with other meal for making coarse bread, and a small quantity of them is generally mixed with new wheat when ground to flour; the millers pretend that soft wheat will not grind well without beans, and they generally contrive that there shall be no deficiency in the necessary proportion. This practice is well known to bakers and dealers. Bean meal mixed with water, and given to cows, increases the quantity of their milk.

2406. *The bean contains much more nutritious matter than most other vegetables.* From the analysis by Sir H. Davy, more than half its weight consists of principles fit for nutriment. Ripe beans contain, according to Einhoff, 84 per cent. of nutritive matter, of which 50 is pure farina, the rest chiefly gluten and mucilage; when young, they are tender and digestible, but when old they become tougher, and prove flatulent to some persons. They are often eaten with bacon or pork by the country people of England, with whom this is a favourite and wholesome dish, the farina of the bean correcting the oily nature of the bacon. The epidermis or skin becomes tough as the beans get old, and, containing a bitter, should be removed.

2407. *The Kidney Bean* (*Phaseolus*, Linn.).—Two species of kidney beans are cultivated in England: the dwarf kidney, usually called the *French bean*; and another, somewhat larger, called the *scarlet runner*, distinguished by the beauty of its flowers, and long cultivated for them before it was used as food. The first (*Phaseolus vulgaris*) is a native of India; and the second (*Phaseolus multiflorus*) was brought from South America in 1633, being first cultivated by Tradescant, the celebrated gardener, at Lambeth; it is the hardiest of the two. In England, the unripe pods of both, but particularly the French bean, are cooked whole in the green or unripe state. In France, where both kinds of kidney beans are cultivated extensively in the fields, the seeds are suffered to ripen, and, under the name of *haricot blancs*, form part of a great variety of dishes, and are much esteemed as very nutritious food; but the green pods used by us are not so. The scarlet runners are also with us dressed in the pods, and have the advantage of being procurable for a longer time than the French bean. They are also the sort most esteemed in France for haricots, their seeds being more farinaceous than the dwarf. (See "*Le bon Jardinier*," 1835, p. 242.) The French bean is wholesome and nutritious in a fresh state, rarely disagreeing with any one for whom vegetables are proper, and may be readily preserved for winter use or sea voyages by salting in casks. For this purpose the large-podded Dutch white runner is preferred. See Book X., "Preservation of Food."

2408. *Lentils* are not used as the food of man in England, though they are on the Continent, where they are cultivated for soups and other culinary preparations; but they are of a larger kind than ours, which are considered as the best food for pigeons.

Sect. IV.—Esculent Roots.

2409. *The roots of many plants supply food, and hence are called esculent.* Those cultivated in Britain may be divided into two groups: the *farinaceous*, as the potato and the Jerusalem artichoke, to which may be added the yam; and the *succulent*, as the turnip, carrot, parsnip, beet, radish, and a few more of less importance. This class of culinary vegetables is that on which the British people chiefly depend; and it is that which is decidedly the best suited to the climate. The potatoes and other esculent roots grown in the British islands are very far superior to those of the Continent in quality, and the quantity consumed is much more considerable.

Subsect. 1.—*The Potato* (*Solanum Tuberosum*).

2410. *The potato, a well-known tuber, popularly, though not with botanical correctness, considered as a root,* may be ranked next in importance to corn as a vegetable food. There is no doubt that it was originally brought to Europe from South America; but its early history has been involved in some obscurity, partly from their being another root very similar, the sweet potato (*Convolvulus batata*), with which it had been confounded, and from which it appears to have received its name.

2411. *The batata* was originally a Malayan plant, and was imported into England from Spain and the Canaries long before the introduction of the potato. It was esteemed a great delicacy, and made into a confection, and is still partially cultivated in Spain and the south of France. It was this that was alluded to by Shakspeare in his Merry Wives of Windsor, "Let the skye rain potatoes, and hail kissing-comfits."

2412. *The true potato is said to have been first brought into this country* from Virginia by Hackluyt in 1584, and planted by Sir Walter Raleigh on his estate at Goughall, near Cork, in Ireland, where it was cultivated to a considerable extent before its value was known in England. Gerarde, in his Herbal (1597), mentions it as "a delicate dish;" and Parkinson, in 1629, says that they were roasted, and then steeped in sack and sugar, or baked with marrow and spices. For many years afterward they were considered as inferior to the Jerusalem artichoke; and, indeed, it was not till the middle of the eighteenth century that they came into general cultivation. Even so lately as the beginning of the nineteenth century, a strong prejudice against potatoes existed in France, though now they are cultivated there to a great extent, and a market in Paris is exclusively devoted to their sale.

2413. *The question as to what is the indigenous country of the potato is now set at rest*, by its being found abundantly in the wild state in the highlands of Chili and Peru, from whence tubers were sent by Mr. Caldcleugh in 1828, and planted in the garden of the Horticultural Society. Potatoes in their wild state in America are of a very small size, and by no means of an agreeable taste. The varieties which we now find in the markets are entirely the result of cultivation.

2414. *The potato has now been introduced into almost every quarter of the globe*, and its cultivation has made the most rapid progress of late. It is the more valuable, as it grows readily in almost every climate, and its culture is extremely easy; it has also this grand advantage, that it will succeed on land which will not produce grain, and may be raised at a small expense. A given quantity of land planted with potatoes will produce as much food as twice that quantity sown with wheat.

2415. *It forms a wholesome food*, and, having no great peculiarity of taste, is relished by every palate; hence it is now a regular standing dish at every table; with many, particularly in Ireland, it serves as a substitute for bread.

The most correct opinion respecting the nutritive properties of potatoes will be obtained from the consideration of their constituent principles. They have been analyzed by various chemists: the analysis by Einhoff, which is generally received as the best, is, in 100 parts, water, 72·6; starch, 15·0; fibrous matter, 7·0; albumen, 1·4; mucilage, 4·0. Here it is essential to observe the large proportion of water, and it is only the remainder that is to be considered as farinaceous. Tartaric acid is abundant in the potato apple; and it is important to notice that the young shoots of the potato yield *Solanea*, an alkali which is, to a certain degree, poisonous.

The fibrous part appears to be a peculiar modification of starch, which, as well as that substance, may be employed for food; but it is to be noticed that there is no gluten, except the albumen may be considered as nearly the same thing. Various kinds of potatoes afford these constituents in proportions a little different; but the above may be considered as the average of the best mealy potatoes, the nutritive part being about twenty-seven per cent., of which the starch is the principal portion. No doubt can be entertained of their wholesome nature, when we consider the numerous hardy peasantry of Ireland, many of whom subsist entirely upon this useful vegetable. It must not, however, be imagined that potatoes contain the same nutritive powers as bread, weight for weight. It has been estimated, as the result of experiments, by two French chemists, MM. Percy and Vauquelin, that one pound of good bread is equal to two pounds and a half or three pounds of potatoes; that seventy-five pounds of bread and thirty of meat are equal to three hundred pounds of potatoes.

2416. *A considerable deduction must be made from the advantages of potatoes*, on account of their requiring much manure for their cultivation, together with the difficulty of transporting and preserving them in consequence of their bulkiness. The time occupied by labouring people in cooking them in the usual way is also a drawback from their usefulness. From their want of gluten, they cannot be fermented alone into bread, but they are advantageously mixed with wheat flour for this purpose.

2417. *London is well supplied with potatoes* from various parts of the country; and the varieties are so numerous, that almost every town has some sort peculiar to its vicinity, the names varying in different districts. They are distinguished as being *farinaceous* or *mealy*; *glutinous* or *watery*; or, according to the ripening, *early* and *late*. Those varieties that are mealy are most esteemed, afford the most nutriment, and are most easily digested; the waxy kinds are inferior in all these particulars. New potatoes are less mealy and less digestible than old ones.

2418. *The earliest potatoes* are cultivated by the gardeners: of the field potatoes, among the most remarkable early sorts are the *early kidney*, *nonsuch*, *early Shaw*, and *early champion*, which last is more generally grown near London. Among the best sorts of late potatoes are the *red round kidneys*, the *large kidney*, the *bread fruit*, &c. The most mealy sorts are the most nutritive, as containing the greatest quantity of starch, and they are likewise the most digestible. The kinds called waxy are said to be very improper for dyspeptic persons.

2419. *In England potatoes are most frequently brought to table boiled plain;* but in *France* they are cooked in a great variety of ways, and furnish many very agreeable dishes.

The boiling of potatoes in the best manner, which to some may appear an operation of no difficulty, requires considerable attention; and much of the goodness of this vegetable depends upon its being properly cooked. The Irish have long had the reputation of being particularly successful in this part of the culinary art. The directions given in the Farmers' Magazine, vol. v., p. 191 and 503, are as follows: "It is of consequence that they be as nearly as possible of one size; that they be well washed and cleared of earth or dirt; that they be put, with cold water, into a pan or kettle, well rinsed about, and kept there for an hour or two, which will extract the black liquor with which they are impregnated. They ought then to be put, with their skins on, not into boiling water, like greens, but into fresh cold water, with a little salt, and boiled in a kettle or saucepan, closely covered, in the most rapid manner. No more water should be put in than merely to cover them, as they produce themselves a considerable quantity of fluid. When sufficiently done, the water should be instantly poured off, and the vessel containing the cooked potatoes is to be placed on the side of the fire, with the cover off, until the steam be completely evaporated; the potatoes are thus rendered quite dry and mealy." There is some difference among cooks in England in the mode of boiling them. Some pare them when raw, like turnips; but this renders them tasteless and insipid; and some think they should be boiled slowly, and for this reason throw in occasionally a little cold water to check the boiling when too fast, which is apt to crack the outside, and let in the water before the heart is done.

2420. *Cooking them by steam* is a good method, as, should they break, to which they are very liable, they cannot imbibe such a quantity of water, and are therefore more easily obtained in the floury state, which is generally preferred.

2421. *Roasting* is another very excellent mode; and Dr. Paris considers it as the best way of preparing them for invalids. Sometimes they are parboiled, and then roasted. *Baking* is not so good a mode of cooking them. They are perhaps the only root grown in Britain which may be eaten every day without satiating the palate.

2422. *Potatoes in their raw state* contain an acrid matter, which is deleterious in some degree even to cattle.

2423. *Potatoes are employed in some other ways*, as largely in the manufacture of bread; see Book IX., "On Bread;" also for starch, see Book XXII., "Laundry."

2424. *Potato flour is, in fact, dry starch powder* procured from the potato, and is much used in Paris in fine bread and pastry: it is also sold in the shops here, but often as arrow-root, to which it is inferior. It is said that several other articles found in our shops are only potato starch, as *Bright's nutritious farina*, *Indian corn starch*, &c.; these are sufficiently wholesome and light, but not very nutritive. Potato starch is easily convertible into sugar; but this is much inferior in sweetness to that of the sugar-cane. It is clammy, and has something of a floury appearance; but, being very white, it is said to be employed by the grocers for adulterating. It is also used for distilling ardent spirits, and for the making of beer. The refuse of the potatoes, after the starch has been extracted, has been found useful in scouring woollen cloths without hurting their colour; and the water decanted from potato starch is excellent for cleaning silks with the smallest injury to the colour.

For the effects of frost on potatoes, see Book X., "On the Preservation of Food."

Potatoes have been found to be an excellent preventive of scurvy, cooked in the ordinary way, or baked under ashes.

2425. *The sweet potato* (*Convolvulus batata*) is a tuberose root common in tropical countries, but of quite a different species from the common potato. It forms a sweet, nourishing food used as potatoes. This plant had been introduced into England by Sir Francis Drake and Sir John Hawkins before the common potato; but, though it is cultivated in other parts of Europe, our climate was found to be too cold for its growth in the open air.

SUBSECT. 2.—*Jerusalem Artichoke* (*Helianthus Tuberosus*, Linn.).

2426. *Notwithstanding the name, this plant is no way allied to the artichoke*, but is of the same genus as the sunflower, and much resembles it. The term Jerusalem is a corruption of girasole, the Italian name for sunflower; and it derives the appellation of artichoke from some agreement of its taste with that of artichoke bottoms. The root, which is the part that is eaten, consists of a cluster of tubers in shape somewhat like the potato; and there are often thirty or forty together. It is a native of Brazil, having been brought to England in 1617; and, before potatoes were so generally adopted, was much in use. It was at first called the Canada potato, to distinguish it from the common potato, which was called the Virginian potato, to which it was at first greatly preferred. It is wholesome and of an agreeable taste, though it is never dry and mealy like the potato, but rather moist and soft in its texture; and, when they do not disagree, they are nutritious. They are extremely productive, and succeed in almost every soil: when once planted, being a hardy perennial, they will continue to flourish without requiring much manure or attention. They likewise form a nutritive food for horses, hogs, &c., containing much farinaceous matter.

SUBSECT. 3.—*Yam* (*Dioscorea Sativa*, Linn.).

2427. *This tuberose root is extensively cultivated in the West Indies, Africa, America,* and *the East Indies*, where it is eaten, roasted or boiled, as a substitute for bread. Its taste nearly resembles that of the potato, but it is rather sweeter, and of a firmer texture. The root is flat, and often palmated or divided somewhat like fingers, and about a foot across; a variety called the *winged yam* is three feet long, and weighs thirty pounds. It is a native of India, where it grows in the woods, and was carried to the West Indies. It is sometimes imported into this country, but rather as an article of curiosity. When fresh, it contains an acrid juice, which causes itching if applied to the skin; but, by heat, this acrid principle is wholly dissipated; and, as it contains a great deal of farinaceous matter, it forms a light, nutritious, and palatable food, either boiled or roasted. Yams are also made into puddings. In Otaheite, a favourite dish is made of them with scraped cocoanut and the pulpy fruit of the banana.

SUBSECT. 4.—*Turnip* (*Brassica Rapa*, Linn.).

2428. *Turnips grow wild in England*, but these cannot by cultivation be brought to resemble exactly the cultivated vegetable. It is said that they were brought here from Hanover. Turnips contain mucilage, little or no gluten, but a good deal of sugar, though the quantity of the latter varies exceedingly, and is not so considerable as in the carrot. The quantity of nutritious matter, upon the whole, in turnips is small; according to Sir H. Davy, only 42 parts in 1000. They are an excellent culinary vegetable, much used all over Europe, and are either eaten alone, mashed, or cooked in soups and stews. A hot climate does not seem to agree with them; and in India they and many of our garden vegetables lose their flavour, and are comparatively tasteless. The Swedish is the largest variety, but too coarse for the table; it is excellent for cattle. The green leaves of the turnip, gathered young in the spring, make good greens, well known by the name of *turnip tops*. The leaves for greens are good from any of the varieties, but are less acrid from the Swedish. Turnips grown in the field will be found of a better flavour than those produced in the garden; and the same remark applies to all the brassica tribe, with the exception of the cauliflower and broccoli, as also to potatoes and tuberous roots.

2429. *The French navet* is a variety of turnip (*Brassica napus esculenta*), but has more the shape of the carrot. It is of a very fine flavour, and is much esteemed on the Continent for soups and made dishes. Two or three of them will give as much flavour as a dozen common turnips; stewed in gravy, it forms an excellent dish. The peculiar flavour resides in the rind; consequently, this is not cut off, but only scraped. The *navet* was once grown here; at present it is seldom to be found in our gardens, though very deserving of being cultivated. It is of a yellowish-white colour, and resembles the carrot in form. It is often, on the Continent, served up with them as ornamental, on account of the contrast of colour. It is sometimes imported to the London market.

Subsect. 5.—*Carrot* (*Daucus Carota*, Linn.).

2430. *A wild carrot* grows in England in sandy soils, but it is small, white, and stringy, and of a strong flavour. Our garden carrot was introduced by the Flemish refugees who settled at Sandwich in the reign of Queen Elizabeth. This plant was so esteemed that the ladies wore the leaves as ornaments in their headdresses. At present a pretty winter ornament is made from the carrot, by placing a slice from the top of the root in a shallow vessel of water, when the young and delicate leaves shoot out, and form an elegant radiated tuft.

2431. *The carrot contains a larger proportion of sugar than any of the corn plants:* in 1000 parts they have 95 parts of sugar, and 3 of starch; this is about six times as much as is found in potatoes; hence a large quantity of spirit can be distilled from them, about half a pint from ten pounds, and they may be used instead of malt for beer. Attempts have been made to obtain the sugar in a crystallized state, but without success.

2432. *Their value in the culinary art is well known;* they are extremely useful in soups and stews. When eaten alone, they should be well boiled, and not too old, as they contain a large proportion of fibrous matter which does not digest very easily. Cattle are extremely fond of them, and they form an excellent fattening food.

2433. *M. Vilmorin of Paris has lately introduced two good varieties* of the carrot, the short yellow and the violet. The latter, which he obtained from Spain, grows to a large size, and is remarkably sweet. The carrot is cultivated by some farmers in their gardens for the purpose of colouring butter; but this is the large red variety, or field carrot. The orange carrot is the kind usually cultivated as a garden vegetable, and is of a more delicate flavour.

2434. *When a carrot is cut across*, it will be seen to consist of two parts, the outer one reddish, and the inner more yellow; the first answers to the bark of wood, and is the most pulpy and sweetest; the latter is the wood itself, and is more stringy. The greater the proportion of this external part in any variety, the more valuable it will be. The carrot may be kept in a succulent and fresh state for a long time, nothing more being necessary than to bury it in sand, and protect it from the frost.

Subsect. 6.—*Parsnip* (*Pastinaca Sativa*, Linn.).

2435. This also is a native British plant, being often found growing by the road-side; but it has not altered so much as the carrot. It is generally used with salt fish in Lent.

2436. *It contains still more sugar than the carrot*, and some persons dislike it on account of its peculiar sweet taste. Besides its use at the table, a pleasant beverage can be brewed from it with hops, as is practiced in the north of Ireland: it will also furnish an ardent spirit and wine. In Scotland, parsnips and potatoes are beat up with butter into a dish for children, who are remarkably fond of it. They are excellent fried.

2437. *The Guernsey parsnip* appears to be an improved variety: it grows there to the length of four feet, and three or four inches in diameter. When parsnips are grown in a poor soil, they lose much of the rank taste which they acquire in richer ground; and when they are roasted, as they are in the north on peat ashes, they become sweet and agreeable, and almost as farinaceous as potatoes.

Subsect. 7.—*Beet Root.*

2438. *There are two varieties of the beet commonly cultivated;* one having a large fleshy root (*B. vulgaris*, Linn.), and the other producing large succulent leaves (*B. cicla*), which we arrange among the spinaceous plants.

2439. *The common beet root* is of a fine red colour, and is originally a native of the sea-coast of the south of Europe, growing wild all along the coast of the Mediterranean. It was brought into this country, in 1656, by Tradescant. It is chiefly employed in England as a garnish for salads and other dishes, on account of the beauty of its colour, and it is also used as pickle. On the Continent it is sometimes boiled sliced, and eaten cold with oil and vinegar; when warm, boiled or baked, its taste is mawkish, and it is said to be not very wholesome if eaten in any quantity.

2440. A variety of beet root called *mangel wurzel* is a coarser kind, grows to a very large size, and is cultivated in the fields for cattle. An improved and smaller variety, which has a red skin, and when cut through is white or veined with white, is extensively employed in France for the manufacture of sugar. See "Sugar," Chap. XIII., Book VII.

From their containing so much saccharine matter, they may be made available for the production of beer or of spirits instead of malt. The French greatly esteem a sort called *castelnandin*, which is said to have the flavour of a nut.

Subsect. 8.—*Radish* (*Raphanus Sativus*, Linn.).

2441. The radish is supposed to be a native of China, but has long been cultivated here. They contain little else than water, woody fibre, and acrid matter, which resides in the external part; they cannot, therefore, be very nutritive, but they may prove a useful stimulant. There are various kinds, but they are generally divided into the turnip and spindle-rooted radish. Many are forced for the early market, and the young seedling leaves are sometimes used for small salad. The seed pods, when green, used to be pickled as a substitute for capers, and formerly the leaves were boiled as pot-herbs. The colour of radishes varies extremely; passing from white to red, and through every shade of that to a dark purple, approaching to black. Professor Burnet states that the roots when boiled and served with toast and butter, and seasoned with pepper, have much the taste of sea kale or asparagus, and form a very palatable dish.

Subsect. 9.—*Skirret* (*Sium Sisarum*, Linn.).

2442. This root is composed of several tap roots, the size of the little finger; and, though now little used, was formerly much esteemed boiled and served up with butter. Worlidge, in 1682, speaks of them as the "sweetest, whitest, and most pleasant of roots." It is a native of China.

Sect. V.—spinaceous plants.

The name of this tribe is derived from spinach, the principle plant among them.

Subsect. 1.—*Spinach* (*Spinacia Oleracea*, Linn.).

2443. *A wild spinach grows in England*, somewhat different from the garden variety, but cultivated in Lincolnshire in preference. The leaves are used as spinach, and the young shoots as asparagus. Spinach is known to have grown here at an early period; and in the monasteries on the Continent it was employed, in 1351, as we do at present.

2444. *The leaves of the garden spinach* are softer and more succulent than any of the brassica tribe. There are three principal varieties; one, the *common spinach*, having the leaves round; *another*, having long triangular leaves; the third is called *Flander's spinach*, and has remarkably large leaves; the round-leaved is procured in the spring, and the long-leaved in the winter. Spinach forms a useful ingredient in soups, and the leaves are also boiled alone and mashed as greens.

2445. *Orache*, or *mountain spinach*, is a hardy sort, much esteemed in France, that produces abundance of large leaves, and forms an excellent summer vegetable. It is a native of Tartary, introduced in 1548. There are two varieties, the white and the red: the young and tender stalks are eaten as well as the leaves.

2446. *New-Zealand spinach* (*Tetragonia expansa*) was discovered in New-Zealand by Sir Joseph Banks, who brought it to England. It is found to grow here perfectly well in the open air, and its leaves are larger and more juicy than the common spinach. It produces fine succulent leaves in the hottest weather in great luxuriance, and has the advantage of being in season when the common spinach is not.

2447. *Chenopodium Quinoa.* This variety is not only useful in its leaves for spinach, but the seeds of the yellow variety are excellent when used as millet, and it bears them abundantly.

Subsect. 2.—*White Beet* (*Beta Cicla*, Linn.).

2448. *This variety of beet is distinguished by its large succulent leaves*, which alone are eaten, and not the root, which is small. It is cultivated in gardens as a culinary vegetable, and is boiled as spinach, or put into soups. It is less known here than on the Continent, where, in many parts of Germany, France, and Switzerland, it forms one of the principal vegetables used by agricultural labourers and small occupiers of land.

2449. A large variety, known by the name of *Swiss chard*, produces numerous large succulent leaves, which have a solid rib running along the middle. The leafy part being stripped off and boiled, is used as a substitute for greens and spinach, and the ribs and stalks are dressed like asparagus or scorzonera, or sliced and stewed; they have a sweetish taste like sea kale, and are more wholesome than the cabbage tribe; but some consider them as having an earthy taste, and, upon the whole, they are not much esteemed. Cattle are very fond of the leaves, which occasion them to give much milk without affecting its taste like turnips or cabbages.

SUBSECT. 3.—*Sorrel* (*Rumen Acetosa*, Linn.).

2450. *Sorrel is much used in French*, and but little in English cookery. It grows wild in our meadows, but is sometimes cultivated in the garden. The leaves are remarkable for their acidity, and are much employed on the Continent in soups, sauces, and salads; but the French sorrel is different from ours, being round-leaved, and very superior in flavour to our common garden sorrel.

2451. *The acid juice contained in the common sorrel* just mentioned, and likewise in another variety called wood sorrel (*Oxalis acetocella*), is what chemists term an oxalate of potash, or, more strictly, a binoxalate of potash; that is, it consists of potash combined with the oxalic acid. This salt, existing ready formed in the plant, though in a state of solution in the juice, may be procured in a dry state by evaporation; and it is then popularly named *salt of sorrel*. Large quantities of it are prepared from wood sorrel in Switzerland and other neighbouring countries; sixty or seventy pounds of leaves yield about five ounces of the crystallized salt. With sugar and water the salt of sorrel forms a pleasant beverage; and in consequence of its having been substituted for lemons for purposes of this kind, it has obtained the very absurd name of *essential salt of lemons*, though having nothing to do with the lemon. But it is proper to state that one of the component parts of this salt, namely, the oxalic acid, is a deadly poison; and that, although the oxalate of potash is not so dangerous, it is by no means safe to use it in any quantity, and therefore very improper to employ it in any way in drink, though it has been ignorantly recommended to make a refreshing beverage in febrile diseases, or as imparting flavour to punch. If the result has not proved fatal, is has probably been because the quantity taken was small.

2452. *The most useful property possessed by the salt of sorrel* is that of taking out spots of ink or iron moulds from linen: it is also used by the cook in flavouring, instead of the leaves.

The process by which the salt of sorrel is obtained is very simple. The expressed juice of the leaves, being diluted with water, is suffered to remain at rest for a few days until the feculent parts have subsided; or, if greater despatch be necessary, it is clarified with the whites of eggs. When the liquor is sufficiently clear, it is drawn off and evaporated by boiling, until a pellicle appears on the surface. It is then set in a cool place to crystallize. When the first crop of crystals has been obtained, the liquor which remains is again evaporated and crystallized; and so the process continues until no more of the salt can be separated.

In the late Professor Burnett's Botany it is stated that, since Scheele discovered that oxalic acid may be formed by acting on sugar with nitric acid, his process, being far the most economical, has in general superseded its extraction from the plant.

SUBSECT. 4.—*Patience Dock* (*Rumen Patientia*, Linn.).

2453. This is called by the Germans winter spinach, and is a hardy perennial plant, the leaves of which may be cut several times in a season. It was formerly much used mixed with sorrel, but is now neglected.

SECT. VI.—ALLIACEOUS PLANTS.

2454. *This tribe*, which takes its name from *allium*, the onion, is distinguished by their bulbous roots, and the high pungent flavour of their bulbs and leaves. They consist of the onion, leek, chive, garlic, and shallot. These plants are, perhaps, more generally diffused all over the world as an article of food than any other; and, from the Indus to the northern tribes of Asia, they were always held in high estimation.

SUBSECT. 1.—*Onion* (*Allium Cepa*, Linn.).

2455. The onion was cultivated in very remote times, having been known to the ancient Egyptians, who worshipped it under some mystic signification 2000 years before the Christian era. It forms a favourite food in Egypt, and in various other parts of Africa, where it is distinguished by its delicate flavour. It is not known when onions were first introduced into England, but they have been long used, and esteemed chiefly as a seasoning for various dishes.

2456. The onion contains much nutritive mucilage. It is much more succulent, and of a milder flavour in warm climates than with us. Those imported from Spain and Portugal are large and mild, and those from Strasburgh are much esteemed. These varieties, when planted in England, degenerate, and become smaller and more pungent. Onions are wholesome employed in any way; they are eaten raw by labouring people, and in this state are strongly stimulant. When young they are sometimes introduced into salads. The large mild kinds, called Spanish onions, are often boiled or roasted, and are considered as an agreeable and nutritive food. They become much more succulent, and their peculiar smell and taste are nearly destroyed, after having undergone culinary preparation. They form one of the most essential productions of the kitchen garden; but the odour which they communicate to the breath is a great objection to their use in the raw state: the best way of removing it is by chewing a little raw parsley.

2457. *The potato onion* is a curious variety, multiplying by numerous bulbs, like the potato.

2458. *The Ciboule*, or *Welsh onion*, never forms any bulb at bottom, and is only cultivated to be drawn as young green onions for salad in the spring: its taste is, however, stronger than the garden onion. It is very hardy, surviving the severest winter, in which, though their blades be cut off, the roots remain sound, and shoot out vigorously in the spring.

2459. *The onion has been analyzed* by Fourcroy and Vauquelin, and found to contain water, sulphur, phosphoric and acetic acids, some vegeto-animal matter, and a little manna; to the latter is owing the sweetish taste observable in onions, particularly in pickled onions, when the acrimony has been extracted by the vinegar.

Subsect. 2.—*Leek* (*Allium Porrum*, Linn.).

2460. The leek is supposed to be a native of Switzerland. Shakspeare, in Henry V., mentions it as the badge of the Welsh before his time, and derives the origin of this from the battle of Cressy. Its hardiness and pungency have recommended it in cold mountainous districts, and it was an ingredient in two very old Scotch dishes, "Cock a leekie," a great favourite with James I.; and in the famed "Haggies." The leeks which are cultivated in the colder parts of the Highlands of Scotland, and in Wales, are more pungent than those of England. Worlidge observes of Wales, "I have seen the greater part of a garden there stored with leeks, and part of the remainder with onions and garlic." Tradition says it was introduced into that country by St. David.

2461. Many prefer its flavour to that of the onion in broth; and, as it stands the winter, it is a very useful pot-herb. Leek porridge is a very ancient dish. The whole plant is used in soups and stews, but the blanched stem is most esteemed; these are very good boiled, and served up on toasted bread and white sauce. Notwithstanding its unpleasant odour, it is very wholesome, but requires to be well boiled, that it may not taint the breath.

Subsect. 3.—*Chive* (*Allium Schœnoprasum*, Linn.).

2462. This is the smallest of the onion kind, rising but a few inches high: it is a native of Britain, and is found occasionally in our pastures. Its taste much resembles that of the onion, but is milder. The bulbs are extremely small, and in clusters. Both these and the leaves are employed as a pot-herb, and as they are very hardy and easily cultivated, they would be very useful in the garden of the cottager, were he accustomed to live more upon broths. The leaves rise early in the spring, and are sometimes employed in spring salads, and also in omelets and soups.

Subsect. 4.—*Garlic* (*Alium Sativum*, Linn.).

2463. This gives its name to the alliaceous tribe; it possesses the most acrimonious taste of the whole, and a smell that is considered by most persons offensive. It grows naturally in Sicily, the South of France, and other countries bordering on the Mediterranean; it was introduced into England in 1548. It is extensively used as a seasoning herb on the Continent, particularly in Italy, and was more relished by our ancestors than in our times. The root, which is the part made use of, consists of a group of several bulbs called *cloves of garlic*, enclosed in a common membranous skin. In foreign cookery it is seldom employed in substance, but introduced for a short time only into the dish that is cooking, and withdrawn when it has communicated a sufficient flavour. At present the French use it much, and consider it essential to many dishes.

Subsect. 5.—*Shallot* (*Allium Ascalonicum*, Linn.).

2464. This was originally found growing wild near Ascalon in Palestine, whence its botanical appellation, and is supposed to have been brought to England by the Crusaders. It is a bulbous root, resembling the garlic in being divided into several cloves enclosed in a skin. The leaves wither in July, when the roots are full-grown: the latter are taken up in autumn, and are dried and housed for use: they will keep till the spring. Its flavour is more pungent than that of the garlic, but more agreeable. It is employed in soups and made dishes, also in sauces and pickles; and it forms a favourite accompaniment to steaks and chops. It was called by old authors the *barren onion*, from the circumstance of its scarcely ever sending up a flower stalk.

Subsect. 6.—*Rosambole* (*Allium Scorodoprasum*, Linn.).

2465. This bulbous root has a flavour between that of the shallot and garlic, and, like them, is divided into cloves: its uses are also similar. It is a native of Denmark, but is cultivated here occasionally.

Sect. VII.—Asparaginous Plants.

2466. *The name of this division is derived* from the practice of the ancients, who called all young sprouts of vegetables by the term asparagus, although this name is now confined to a particular species. This class comprehends *asparagus*, *sea kale*, *artichoke*, *cardoon*, *rampion*, and *alisander*. In all of them it is only a small portion of the vegetable that is eaten, and that most generally in a young and undeveloped state; they belong to the class of luxuries rather than of necessary food, and they are brought to perfection only by great care and attention on the part of the gardener, and at a considerable expense in preparing the ground. In their wild state they are chiefly seashore plants unfit for human food.

SUBSECT. 1.—*Asparagus* (*Asparagus Officinalis*, Linn.).

2467. *Asparagus*, often, in London, vulgarly and absurdly called *sparrow grass*, is a vegetable highly esteemed and largely cultivated in the garden for the London market. It has been so much improved by cultivation that the original plant from which it has been derived could not be recognised except by the botanist.

2468. Wild asparagus is a very small vegetable that grows in poor sandy soils both in North and South Britain, on the seashore, but is not very common. In the saline and sandy steppes of Russia and Poland it is abundant, and is fed on by horses and cattle. The Romans had asparagus of very large size, and it was cultivated with great success in Holland, but it is now grown in greater quantities in the environs of London than anywhere else in the world; at Deptford and Mortlake there are hundreds of acres planted with this vegetable.

2469. The part which is eaten is the young shoot, as far as the flower not yet developed. Asparagus is a light, digestible food, but not particularly nutritious. The tops of the shoots are not blanched in this country, but in Spain the whole is blanched by placing pieces of cane over it.

SUBSECT. 2.—*Sea-kale* (*Crambe Maritima*, Linn.).

2470. *This plant is so named* from its growing naturally *on our seashores*, particularly in the West of England, and near Dublin. The young spring shoots just as they begin to appear, and the stalks of the unfolded leaves, then blanched and tender, are the parts that are cut off and boiled for use. Though collected by the peasants, and eaten as a pot-herb time out of mind, and even cultivated in the garden, yet it appears that it was Dr. Letsom, in 1767, who first gave it a good character, and that it did not come into high repute until 1794. It is now in very general use, and, within the last ten or fifteen years, has become a very common and cheap vegetable. It is one of the most valuable esculents indigenous to Britain.

2471. *It is dressed and eaten in the manner of asparagus*, and the shoots are usually blanched; but it requires to be very well boiled, as it is naturally hard. It is easily cultivated, and forced in the winter season; and it is a great luxury at table, since in that season many vegetables are difficult to be procured. It might be produced in many places on the seashore, where no other edible vegetable would grow, seeming to prefer a poor sandy soil. The flowers form a favourite resort for bees.

SUBSECT. 3.—*Artichoke* (*Cynara Scolymus*, Linn.).

2472. *Like the sea kale, the artichoke is a maritime plant*, and succeeds best when manured with sea-weeds. It was probably brought from the Mediterranean and cultivated in England about 1580. The part which is eaten is the flower head in an immature state; what is called the *artichoke bottom* is the fleshy receptacle, which is surrounded by the bristles and seed down, vulgarly called the *choke*, and by also a soft substance on the lower part of the leaves of the calyx. In England artichokes are boiled plain and eaten with melted butter and pepper; the bottoms are also stewed in milk; occasionally they are pickled. The French fry them and use them in ragouts; or thin slices of the bottoms are cut off, each having a leaf attached, by which it is lifted and eaten raw, as salad. The flowers may be used for coagulating milk. The shoots and young leaves are sometimes blanched by earthing, and eaten as chard. Artichokes may be dried and preserved for use.

SUBSECT. 4.—*Cardoon* (*Cynara Cardunculus*, Linn.).

2473. This plant is a native of Candia, and was brought into England a century after the artichoke. It much resembles the artichoke, but grows higher. It is esteemed on the Continent, but is little used in England; the stalks and ribs of the inner leaves are employed in soups and ragouts. The Spanish cardoon is the best.

SUBSECT. 5.—*Rampion* (*Campanula Rapunculus*, Linn.).

2474. This is a native of England, but not common. The root, which is the part that is eaten, is long, white, and spindle-shaped; it is eaten raw like a radish, and has a pleasant nutty flavour; both it and the leaves are sometimes used in winter salad.

SUBSECT. 6.—*Prussian Asparagus* (*Ornithogalum Pyrenaicum*).

2475. A plant is sold under this name in Bath, and the south and west of England, as a substitute for asparagus. The part which is eaten are the flower stalks before the buds are expanded. They are served up in the same way as asparagus, and are tolerably good, but rather insipid.

2476. *Hop Tops.*—The young shoots of the hop, when they have risen two or three inches, are also employed sometimes as a substitute for asparagus. In Belgium they are blanched; and they are very strongly recommended as an admirable ingredient in a variety of dishes, such as soups, omelets, &c., by an experienced cook from Sardinia, who mentions them in the "Gardener's Magazine."

Subsect. 7.—*Alisander* (*Smyrnium Olusatrum*, Linn.).

2477. This plant also grows naturally near the sea, and somewhat resembles celery in taste The leaves are of a pale green; when blanched, the leaf stalks were formerly much used as a pot-herb and in salad, but it is nearly out of use.

Subsect. 8.—*Bladder Campion* (*Silene Inflata*).

2478. The young shoots of this, when boiled, are an agreeable flavoured vegetable, and are boiled like asparagus.

Sect. VIII.—acetarious vegetables.

2479. *By the term acetaria*, or *acetarious vegetables*, *is expressed* a numerous class of plants of various culture and habits, which are chiefly employed as *salads*, *pickles*, and other *condiments*. They are to be considered rather as articles of comparative luxury than as ordinary food, and are more desirable for their coolness or their agreeable flavour than for their nutritive powers.

2480. *Salads consist* of raw vegetables, of which lettuce is the most generally used with us; but several others are occasionally employed, as celery, cresses, onions, beetroot, &c. As raw vegetables are liable to ferment in the stomach, and as they give but little stimulus to that organ, they are generally dressed with some condiments, as vinegar, pepper, mustard, salt, and oil. Considerable difference of opinion exists among medical men respecting the use of these, and particularly oil, some condemning, others approving it.

Subsect. 1.—*Lettuce* (*Lactuca Sativa*, Linn.).

2481. *The botanical name of the lettuce, Lactuca, is derived* from the milky juice that exudes from its stalks when it is cut. This juice, when the plants are young, is of a mild and pleasant bitter, containing a small quantity of the narcotic principle; but this, in the old stems and foliage, and more especially in those plants which are fully exposed to the sun, becomes extremely bitter and notably sedative. A medicine (*extract of lettuce*) is extracted from it, which is said to have the good without the bad effects of opium. In the strongly-scented wild lettuce, which is uneatable, this is very abundant: the plant is cultivated in Forfarshire for this purpose.

2482. *The lettuce* came originally from the Grecian Archipelago, and the name of one kind, the *cos lettuce*, reminds one of the island of the same name. The soporific qualities of the lettuce were very early known, and a lettuce supper has been thought very conducive to repose.

2483. *There are two principal varieties, the cabbage* and the *cos* lettuce, the latter often vulgarly and improperly called *gauze* lettuce. The first is the earliest in season; the leaves are roundish, and the head flat, and close to the ground. The cos lettuce is more upright, and the head is of an oblong form. When very young, the leaves of both are open, and then the cabbage lettuce is preferred; but both have compact round heads when mature, the inner leaves being white, and then the cos lettuce has the finest flavour, and is most employed for salads, the cabbage lettuce being more used for soups. Blanching them prevents, in a great measure, the formation of the bitter acrid and narcotic principle, and renders them more wholesome.

Lettuces may be considered as a cooling summer vegetable, and useful rather as correcting or diluting animal food than as containing much nutriment of itself. It is generally eaten with some condiments, as vinegar, mustard, oil, &c.

Subsect. 2.—*Endive* (*Chicorium Endivia*, Linn.).

2484. The history of this plant is little known. It is supposed to have come originally from China and Japan, and to have been introduced into England about 1548. It is remarkable for its elegant leaves, which are much divided at the edges. When suffered to remain green by exposure to the light, they are harsh and bitter, but by tying them up with bass, and keeping them well earthed, they become blanched and succulent, and lose the greater part of their bitterness, retaining only enough to be agreeable. It is grown in abundance in the neighbourhood of London, and is much used as a winter salad, and likewise in soups and stews. The French consume a great quantity of it, raw in salads, boiled in ragouts, fried with roast meat, and as a pickle: they esteem it a wholesome esculent. By judicious culture it may be obtained through the winter, when other salads are not easily procured.

2485. *Chicory*, or *Succory*, called also *wild endive* (*Chicorium Intybus*, Linn.), is a native of this country, growing wild by the road-side; and, though little regarded here, it is much cultivated on the Continent. Its leaves, in the natural state, are bitter; but by steeping them some hours in water this bitterness is removed, and still more when blanched. They are used as endive in the Netherlands, and particularly the blanched leaves are sold in the markets as an early spring salad. The roots are scraped and boiled, and eaten with sauce and potatoes.

As chickory is very hardy, easily cultivated, and grows upon very poor land where scarcely anything will thrive, chiefly dry calcareous soils, its cultivation has been strongly recommended by Arthur Young and other writers on agriculture, as a food for cattle.

2486. *Mr. Loudon states that* an acre of chicory might be easily grown upon cheap land five or ten miles distant from the place of consumption. The roots may be brought together early in the autumn, and planted and packed close together in a few hundred feet of garden ground to defend them from the frost of winter; then, by laying on some earth and manure early in the spring, the leaves will push into it in a blanched state, and form a very crimp and early salad, the new leaves being derived from the stock of sap elaborated in the preceding year. The adoption of this plan of cultivating chicory may be recommended to many great towns in the north of England, where anything in the shape of a salad is rarely seen until the end of April, and then only tough green lettuces, far more bitter than this invitingly white chicory. Its growth is so rapid that it may be cut three or four times every year.

2487. Its roots may be laid up in a warm cellar, and, if kept from the frost, it will then soon send out a crop of blanched leaves, from which a salad may be obtained in the winter. This property is also taken advantage of on shipboard; the roots are put into a cask with sand, having the sides pierced with numerous holes (or a hamper will do), and the leaves make their way through the holes; this method of forcing is carried on extensively in France.

2488. But there is another use to which the roots of this plant have been applied. Dried and ground, they are employed to a great extent in Holland and Flanders, and likewise in France, as a substitute for coffee. See Chap. XI., Book VIII., "Coffee."

Subsect. 3.—*Celery* (*Apium Graviolens*, Linn.).

2489. Celery is also a native of Britain: the wild plant is known by the name of *smallage*, and grows on the side of ditches, and in the neighbourhood of the sea; but although it resembles the cultivated plant considerably, it has a rank, acrid, and disagreeable taste, and is even narcotic and unsafe; yet it has been converted by cultivation into the mild aromatic flavour of the garden celery.

2490. *The blanched foot-stalks of the leaves* are eaten raw, and great care is taken to have them in perfection on the table. The blanching of celery is a striking instance of the effect of the want of light in vegetation. All the colouring matter in plants is developed or assisted in its formation by the sun's rays; heat alone will not produce the same effect: it is light that causes the colour, and hence plants that grow in a dark place are always white: it may be observed that the part of the stem of all plants just below the surface of the ground is white, and that the green does not commence till above the surface. To procure the stalks of the celery as white as possible, they are kept almost entirely covered with earth while growing, and only the tops of the leaves suffered to appear above ground. This management also increases their crispness, and renders them milder flavoured. In Germany celery is boiled and served up as a dish, and the Italians use the green leaves in soup. With us the flavour of celery is employed in the culinary art; and when it is required, and neither the leaves nor stems can be had, the seeds bruised are sometimes employed as a substitute. In the neighbourhood of Manchester celery is grown of an enormous size.

2491. *Celeriac* is a variety of celery having the root of a turnip form, the only part that is eaten. It is much esteemed in Germany and other parts of the Continent, where they boil and eat it when cold, sliced with oil and vinegar as a salad, or employ it in various dishes. It is occasionally imported from Hamburgh, but is little cultivated in England, though very hardy.

2492. *Corn salad*, or *lamb lettuce*, (*Felix olitoria*, Willd.). This is a diminutive annual, common in cornfields and sandy soils. It is occasionally cultivated in gardens, rising to the height of a foot, and is used as a salad. It has long been a favourite plant in France.

Sect. IX.—small salad herbs.

2493. There are certain herbs which are used chiefly in the seed leaf, or when extremely young, for the purpose of procuring salads throughout the year, or at times and in situations where no other can be had. Some of these are also mixed with the larger salad plants to improve their flavours or wholesome qualities. The sorts mostly in use in this country are mustard, cresses, rape, turnip, radish, white cabbage, cabbage lettuce, &c. Some of these may be had at all times of the year, and are cut when not more than a week or ten days old. Being mostly of a warm relish, if suffered to grow too large, so as to run into the rough leaf, they become of a disagreeably strong, hot taste.

SUBSECT. 1.—*Mustard* (*Sinapis*, Linn.).

2494. *There are two varieties of mustard*, the black and the white, both natives of this country, and occasionally growing wild in the cornfields. The black is rather a larger plant than the white, and the leaves darker. The seeds of both, but chiefly the former, are ground to produce the well-known condiment, flour of mustard. It is principally cultivated in Durham.

2495. *Mustard contains* a mild fixed oil of a greenish yellow colour, procured by pressure. The mustard cake, after the expression of the bland oil, when distilled with water, yields an acrid, volatile oil, the principles of which reside in the seeds, but cannot be developed without the aid of water. The pungency of the mustard, when used as food, is developed from the action of the emulsion on a peculiar principle in the same manner as the hydrocyanic acid is developed by the action of water on the bitter almond.

2496. *Mustard is one of the best stimulants* employed to give energy to the digestive organs. It was in high favour with our forefathers. In the "Northumberland Household Book for 1512," p. 18, is an order for an annual supply of 160 gallons of mustard.

2497. *Mustard, in its present form, was not known at our tables previously to* 1729. At that time the seed was only coarsely pounded in a mortar, as coarsely separated from the integuments or skins, and in that rough state made up for use; sometimes it was brought to table whole, or boiled in vinegar. It then occurred to an old woman, of the name of Clements, resident at Durham, to grind the seed in a mill, and to pass the meal through the several processes which are resorted to in making flour from wheat. The secret she kept for many years to herself, and, in the period of her exclusive possession of it, supplied the principal parts of the kingdom, and, in particular, the metropolis, with this article. George I. stamped it with fashion by his approval. Mrs. Clements twice a year travelled to London, and to the principal towns throughout England, for orders, as regularly as any tradesman's rider of the present day; and the old lady contrived to pick up, not only a decent pittance, but what was then thought a tolerable competence. From this woman's residing at Durham, it acquired the name of Durham mustard.

2498. *Mustard is remarkable for the rapidity of its growth*, and, on this account, is frequently sown in the ground as a small salad, together with cress. The seeds strewed on wet flannel, and placed in a warm situation, even by the fireside, frequently shoot out their seed leaves in a day or two—sometimes even in a few hours—a circumstance which is frequently taken advantage of in long voyages. Ships going to the East Indies have boxes with earth placed on the deck, wherein they sow mustard and cress for the purpose of getting salad on the voyage; and the number of crops thus raised is surprising.

SUBSECT. 2.—*Garden Cress* (*Lapidium Sativum*, Linn.).

2499. This elegant small plant is not found wild in England, and is supposed to have been brought from Persia or Cyprus, about 1548. It is considered as the principal of the small salad herbs, and is much cultivated for this purpose, having a very warm, but agreeable aromatic flavour. By the assistance of a little artificial heat, it may be had fresh throughout the winter.

2500. *American cress* (*Barbarea præcox*).—This variety grows wild in Britain in moist or watery ground. It is aromatic and pungent, but rather bitter. It is sometimes cultivated for winter and early spring salad. It is also called *French cress*.

2501. *Winter cress* (*Barbarea vulgaris*).—This also is found wild in Britain in watery places and slow-running streams. In flavour and use it much resembles the last

SUBSECT. 3.—*Water-cress* (*Nasturtium Officinale*, Linn.).

2502. Water-cress has long been a favourite vegetable, and is found abundantly on the edges of running streams, preferring clean water to that which is muddy. It should be carefully distinguished from the water parsnip (*Sium nodiflorum*, Linn.), which is poisonous, and is often found growing with it.

2503. *The demand for water-cresses in London*, as an adjunct at the breakfast table, has been so great, that, since 1808, they have been cultivated extensively in various places; as at Springhead Valley, near Gravesend, West Hyde, near Rickmansworth, Hackney, Uxbridge, &c. On a gravelly or chalky bottom, shallow excavations are made, into which running water is introduced about a foot deep, and the cress is planted in regular rows, so that a constant succession of young and healthy green shoots, in great perfection, are provided for the market. It is supposed to possess antiscorbutic properties.

SUBSECT. 4.—*Burnet* (*Poterium Sanguisorba*, Linn.).

2504. This hardy perennial plant is indigenous in Britain, found in dry, upland, calcareous soils, and occasionally cultivated in gardens. The leaves are used in salads, put into soups, and form a favourite ingredient in cool tankards. When slightly bruised, they smell ike cucumber, and they have a somewhat warm taste. They continue green through the winter, but are now little in use.

SUBSECT. 5.—*Rape* (*Brassica Rapus*, Linn.)

2505. Rape, a native of Britain, is sometimes cultivated in gardens, the seed leaves being employed for salad, as mustard and cress. It is warm and aromatic. But the chief value of this plant is in the oil that is expressed abundantly from its seeds by a mill.

Sect. X.—Pot-herbs, or seasoning herbs.

2506. This title includes those vegetables which are not used alone as food, but are employed as additions to soups, stews, and various dishes, to increase their nutritious qualities, or to give them flavour. Many of them would prove actual poisons if eaten in quantity; but they owe their useful properties to their stimulating nature and powerful flavour, by which they render many kinds of food palatable that would otherwise be insipid: some are used medicinally. They are of very ancient use, and are to be found in every garden, from that of the mansion to that of the cottage.

Subsect. 1.—*Parsley* (*Apium Petroselinum*, Linn.).

2507. This herb, of extensive use in the culinary art, was known to the ancient Greeks, but the time of its introduction into Britain is not ascertained. Though not indigenous, it is so common, and so frequently sows itself, as to be frequently taken for a native.

2508. *There are several varieties:* 1. The *plain-leaved*, not much cultivated, though the only one used formerly. It is now nearly banished from the garden, because the curled varieties are much more elegant; but there is another reason for its being laid aside—its great resemblance to a poisonous British weed, the *fool's parsley*, or *lesser hemlock* (*Æthusa cynapium*). The leaves of the latter are of a darker green, and, when bruised, have a very disagreeable smell, quite different from that of the common parsley. When in flower, the fool's parsley is easily distinguished by what is called its beard, that is, by the three long pendant leaves of its involucrum. 2. The *curled-leaf parsley*, which may be safely used, being quite unlike the hemlock; it is the best, both for its flavour and appearance on the dish as a garnish. Sheep, hares, and rabbits are extremely fond of this herb, and it is said to impart to their flesh a fine flavour. It is useful to *know* that parsley is poison to parrots.

Naples parsley, or *celery parsley*, is a variety between parsley and celery, and is used as the latter.

Hamburgh parsley is a variety cultivated for the roots, which grow to the size of small parsnips; these boil exceedingly tender and palatable, are very wholesome, and may be used in soup or broth, or to eat with meat like carrots or parsnips.

2509. *Purslane* (*Portaluca oleracea*, Linn.).—This plant is a native of South America. The young shoots and succulent leaves were more used formerly than at present as a cooling ingredient in spring salads.

Subsect. 2.—*Tarragon* (*Artemisia Dracunculus*, Linn.).

2510. This herb, of a fragrant smell and aromatic taste, is used in France, on account of its pungency, to correct the coldness of salad herbs; an infusion in vinegar makes a good fish sauce, and it is also an ingredient in pickles, and in soups and other dishes particularly in French cookery. It is said to be originally a native of Siberia.

Subsect. 3.—*Fennel* (*Anethum Fœniculum*, Linn.).

2511. Fennel grows wild with us in chalky soils, particularly at Feversham, but has been long cultivated in the garden. The leaves, from their elegance, are often used as a garnish or ornament to various dishes. They are boiled in soups and fish sauces, and some use them as salads. They have too powerful taste in their natural state to be used, except as a flavouring ingredient. The French use it frequently in fish soups; but the Italians, by blanching the plant in their warm climate, where it grows rapidly and to a large size, obtain it in a state very like celery, with a strong thick stalk: the strong taste is then destroyed, and they eat it with oil, pepper, and vinegar

Subsect. 4.—*Dill* (*Anethum Graveolens*, Linn.).

2512. This plant resembles fennel considerably, but is smaller. It is used in pickles, particularly with cucumbers, and sometimes in soups and sauces, but chiefly for medicinal purposes. It is a native of Spain.

Subsect. 5.—*Horseradish* (*Cochlearia Armoracea*, Linn.).

2513. This well-known accompaniment of roast beef is a native of England, and a hardy plant, growing wild in wet ground, but it has been long cultivated in gardens also. It is occasionally used in sauces, and in winter salads. Its acrid taste depends upon an essential oil of great pungency, which may be obtained by mashing and distilling with water

2514. *The oil of horseradish*, which is frequently procured in Sweden, is extremely volatile, quickly evaporates, and fills the room with the peculiar flavour of the plant. On account of the great volatility of its oil, horseradish, when dried, loses its flavour, and becomes unfit for the purpose to which it is applied: hence it should never be preserved by drying, but by keeping moist and cold through burying in sand; and for this reason it is that, when scraped for the table, it almost immediately spoils by exposure to the air, the volatile oil evaporating.

SUBSECT. 6.—*Nasturtium* (*Tropæolum*, Linn.).

2515. This elegant plant, called sometimes *Indian cress*, is a native of Peru, but grows very well with us. Its young leaves and flowers being of a warm nature, are sometimes used in salads, as the cress; its fine yellow flowers are employed to garnish dishes; and its seeds, when pickled, form a good substitute for capers.

SUBSECT. 7.—*Chervil* (*Scandix Cerepolium*, Linn.)

2516. Chervil is a native of various parts of the Continent of Europe, and is sometimes observed naturalized in our gardens. The tender leaves are used in salads, and the curled variety for garnishing. There is a kind cultivated in the gardens of Paris (*Cerfeuil frisé*) with beautifully frizzled leaves. The roots are poisonous.

SUBSECT. 8.—*Pot-marigold* (*Calendula Officinalis*, Linn.).

2517. This is a native of France and Spain, and naturalized here since 1573. The flowers were formerly much used in broths and soups, and the plant is still frequently to be met with in cottage gardens.

SECT. XI.—SWEET HERBS.

2518. *Of sweet herbs some are cultivated for culinary purposes, and others for the perfumer and druggist.* Much of the natural fragrance of the fields is owing to the aroma of this class of plants, the *Labiatæ;* and many of them yield an aromatic essential oil by distillation. The most useful of this class are thyme, sage, mint, marjoram, savory, basil, rosemary, lavender, tansy, and balm. It is said that mint, and many other plants which yield an essential oil, afford it of a more penetrating odour in England than in the south of Europe, and that all strong-smelling plants lose their odour in a sandy soil.

SUBSECT. 1.—*Thyme* (*Thymus*, Linn.).

2519. We have two species of wild thyme in Britain, which differ from the common thyme cultivated in our gardens for culinary purposes.

Garden thyme (*Thymus vulgaris*, Linn.) is a native of the south of Europe; it is a shrubby evergreen about a foot in height, and is more delicate in its aromatic flavour than wild thyme; its young leaves and tops are used in stuffings, soups, and sauces.

Another smaller species, *lemon thyme* (*T. citriodorus*, Linn.), has a strong perfume, like the rind of lemons, and is used for some particular dishes.

A variety called *Frankincense thyme* is cultivated in Norfolk. Thyme was used by the Romans to flavour cheese.

SUBSECT. 2.—*Sage* (*Salvia Officinalis*, Linn.).

2520. Sage is originally a native of the south of Europe, but has been long an inhabitant of our gardens. There are several sorts, as the red, the green, the small-leaved, and the broad-leaved balsamic. Its chief use in cookery is in stuffings and sauces, to correct the too great lusciousness of strong meats, as goose, duck, or pork; its taste is warm, bitterish, and aromatic, qualities which depend upon an essential oil. The red has the most agreeable and fullest flavour for this purpose; the green is the next; the last two are used in medicine. Sage had great reputation formerly on account of its medicinal qualities; but at present these do not appear to be much regarded. It possesses, however, some aromatic and astringent powers; and a decoction, or sage tea, is found serviceable in debility of the stomach, and in nervous cases. The Chinese sometimes prefer it, it is said, to their own tea. It is useful as a gargle in sore throat, and it is grateful and cooling. The broad-leaved balsamic species is the most efficacious for its medical qualities, and as a tea herb. It is also introduced into cheese.

SUBSECT. 3.—*Mint* (*Mentha*, Linn.).

2521. *There are several species of mint* that grow wild in Britain, found chiefly in low, moist situations, and they are likewise cultivated. They are all distinguished by a well-known and peculiar aromatic flavour, and some are employed in culinary preparations; others yield a highly odoriferous and pungent essential oil by distillation. None of them are in the least poisonous; but they are very different both in appearance and their uses.

Spearmint (*Mentha viridis*, Linn.).—This is the common mint cultivated in our gardens, and employed in different processes of cookery, as having the most agreeable flavour; the leaves are sometimes boiled in certain dishes, and afterward withdrawn. They likewise form an ingredient in soups, and are sometimes used in spring salads. They are also dried for the winter, and in this manner lose none of their flavour. Mint is stomachic and antispasmodic, and is useful in flatulencies; these qualities probably led, independently of its agreeable flavour, to its universal use in pea soup, in which it is a valuable ingredient.

Peppermint (*M. piperita*, Linn.).—This is cultivated entirely for the essential oil distilled from it. Its taste is stronger, warmer, and more pungent than spearmint, and leaves a sort of coolness on the tongue after tasting it. It yields a little camphor, to which its taste is partly owing, and its medicinal uses are well known

Pennyroyal mint (*M. pulegium*, Linn.), has a warm, pungent flavour, but less agreea ble than common mint. It is employed in some particular dishes in cookery, and formerly chiefly for medical purposes, but is now little used.

SUBSECT. 4.—*Marjoram* (*Origanum*, Linn.).

2522. *There are several species of marjoram*, but that which is preferred for cookery, and which is cultivated in our gardens for this purpose, is the *sweet marjoram* (*O. marjorana*, Linn.), also called knotted marjoram. It is a native of Portugal, and the seeds seldom ripen here; they are brought from France. The leaves are dried as a seasoning herb, having an agreeable aromatic flavour. There is also a *winter sweet marjoram* (*O. Heracleoticum*, Linn.), a native of Greece, used for the same purposes. *Pot marjoram* (*O. onites*, Linn.) is another variety originally brought from Sicily, which does not ripen its seeds here. *Common* or *wild marjoram* (*O. vulgare*, Linn.) is found growing in our fields, chiefly among copse-wood on calcareous soils. This has nearly the same flavour, but is inferior, and is only used when the others are not at hand. All these are favourite ingredients in soups, stuffings, &c.

SUBSECT. 5.—*Savory* (*Satureja*, Linn.).

2523. Of this aromatic herb there are two varieties, the summer and winter savory, from the time of year when they may be gathered. They are natives of Italy, but are cultivated in our gardens for the use of the cook. The leaves are gathered and dried.

SUBSECT. 6.—*Basil* (*Ocymum*, Linn.).

2524. This plant is highly aromatic, its odour resembling that of cloves. There are two principal varieties, the *sweet* or *larger basil* (*O. basilicum*, Linn.), and the *bush* or *least basil* (*O. minimum*, Linn.), both natives of the East Indies. Though little employed in English cookery, they are favourite herbs with French cooks, on account of their flavour in highly seasoned dishes, and the leaves are used in small quantities in soups and salads. The Chinese, also, are said to flavour their dishes with basil.

2525. *Clary* (*Salvia selaria*, Linn.).—This is a native of Italy. Its leaves are sometimes used in soups, though some dislike its odour. A medicinal wine is made from its flowers.

SUBSECT. 7.—*Rosemary* (*Rosmarinus Officinalis*, Linn.).

2526. This is also a highly aromatic plant, a native of the south of Europe, and derives its name from its beautiful appearance when glittering with dew on the seashore. Its leaves have a fine aromatic fragrance like camphor, of which, indeed, its oil contains one fourth. From an old opinion that rosemary had the property of strengthening the memory, this plant has been made an emblem of remembrance or fidelity; which probably led to the custom in some parts of the west of England and Wales of wearing branches of it at weddings and funerals. Infusions of the leaves are put into some drinks; but its chief use is in the flowers giving their fragrance to Hungary water, used as a cosmetic. It also enters into the composition of Eau de Cologne, and four-thieves-vinegar.

SUBSECT. 8.—*Lavender* (*Lavandula Spica*, Linn.).

2527. Lavender is a highly odoriferous plant, scarcely used in cookery, but is extremely valuable on account of its agreeable perfume. The leaves and flowers are both aromatic, and when dried they are put among linen. From their flowers the well-known perfume, lavender water, is prepared. The ancients employed this plant to aromatize their baths, and to give a sweet scent to water in which they washed; hence their generic name, *Lavandula*. It grows spontaneously in the south of Europe, and has been cultivated in England since 1568: a great deal is grown near London, and sold to the druggists, perfumers, and distillers. The essential oil, when procured pure, is sometimes called *oil of spike*. Sixty ounces of flowers yield only an ounce of this oil; hence its high price and frequent adulteration.

SUBSECT. 9.—*Tansy* (*Tanacetum Vulgare*, Linn.).

2528. Tansy grows wild in Britain, and is cultivated in gardens. Its leaves, having a powerful aromatic bitter, are sometimes chopped or bruised to put into certain puddings, or the juice alone is so employed: its use is very ancient. There are three varieties: the *plain* and *curled leaved*, and the *variegated*.

SUBSECT. 10.—*Saffron*.

2529. This is the dried stigmata of a bulbous plant, the *Crocus sativus*, once much cultivated in England, and used in seasoning dishes in the time of Richard II. It is now chiefly employed as a colouring matter for cheese and butter. It is still cultivated near Glazenwood, in Cambridgeshire, and at Stapleford. When good, saffron has a beautiful yellow colour and an agreeable odour; it yields its active principle, an essential oil, to water and spirit. Dr. A. T. Thomson, in his Materia Medica, states that it excites the nerves of the stomach, and is in some degree narcotic; its incautious use has sometimes been attended with dangerous consequences. It is sometimes adulterated with safflower and marigolds; but the adulteration is easily detected, for the petals of these flowers will appear distinct from the stigmata of the crocus. Some saffron is imported from the Continent, but it is inferior to the English.

Subsect. 11.—*Laurel or Bay Leaves.*

2530. Bay leaves are often mentioned in the receipts for cookery. As there is some confusion with respect to the name, it is necessary to put this matter in a clear light. The name of *Bay* has been applied to two trees very different. The proper laurel-tree (*Laurus nobilis*, Linn.), the classical laurel, is commonly called the bay-tree, or sweet bay-tree; but its leaves, though slightly aromatic, are harmless, and are seldom, if ever, employed in cookery. A species of the genus Prunus (*Prunus laurus-cerasus*, Linn.), a kind of cherry-tree, has leaves much resembling those of the laurel, whence the name *lauro-cerasus*, or *cherry laurel;* this is also sometimes called bay, and is the sort employed for its flavour. The cherry laurel is an evergreen tree, cultivated in gardens; its leaves are large, thick, oblong, glossy, pointed at both ends, and slightly indented. These latter leaves have a bitter styptic taste, accompanied with a flavour resembling that of bitter almonds, or other kernels of the drupaceous fruits. This kernel-like flavour being agreeable, has occasioned them to be employed for culinary purposes, especially in custards, puddings, blanc mange, &c., and then, as the proportion of the sapid matter of the leaf is usually diluted in a large proportion of milk, bad effects have seldom or never ensued from its use. But as the Prussic acid developed by the action of water on laurel leaves is known to be a violent poison, it is necessary that the public should be cautioned with respect to its properties, lest too much should be used on some occasions; since in the process of making laurel water by distillation it is sufficiently powerful to occasion death, and persons have been poisoned bv drinking laurel water by mistake.

Sect. XII.—Plants used in tarts, confectionery, and domestic medicine.

2531. The list of this class of plants, as used formerly, was more considerable than at present, many of those employed by the ancient herbalist having given way to the abundance of foreign spicery and the more powerful medicines of the chemist. Those which we shall describe are still cultivated, and are all useful, particularly in retired situations in the country, where a druggist is not at hand.

Subsect. 1.—*Rhubarb* (*Rheum*, Linn.).

2532. This is one of the most useful and best of all the productions of the garden that are put into pies and puddings. It was comparatively little known till within the last twenty or thirty years, but it is now cultivated in almost every British garden. The part used is the footstalks of the leaves, which, peeled and cut into small pieces, are put into tarts, either mixed with apples or alone. When quite young, they are much better not peeled.

2533. *The culture of the tart rhubarb has increased very rapidly of late*, in consequence of the great demand for it, and, consequently, it is at present sold at a very cheap rate. It comes in season when apples are going out.

2534. There are several varieties of this plant: *common rhubarb* (*Rheum rhaponticum*, Linn.), called also *Monk's rhubarb*, is a native of Asia, but has been cultivated in England since 1573. It is much improved by blanching.

The Hybrid rhubarb (*Rheum hybridum*, Linn.) is also a native of Asia, but from a more northern part. It was first cultivated as a garden plant by Dr. Fothergill in 1778, and is now in general use, the leaves being much larger and more succulent than the common sort. *Elford rhubarb*, or *scarlet rhubarb* (*Rheum undulatum*), is considered by gardeners to have the finest flavour, and, when cooked, is of a bright scarlet; it is free from that peculiar taste which occasions common rhubard to be disliked by some persons. *Turkey rhubarb* (*Rheum palmatum*) is a most elegant plant, but its leaf stalks are small. It is the root of this which forms the well-known medicinal drug, but its virtues are not so well developed in this climate as in Tartary, from which the rhubarb of the druggist is brought to us by the way of Turkey, India, and Russia.

Subsect. 2.—*Gourd* (*Cucurbita*, Linn.)

2535. *The gourd constitutes a large family;* some varieties are very beautiful, and are cultivated for ornament; some grow to an immense size, and are kept more as matters of curiosity, and others are cooked in a variety of ways. In warm climates, and particularly when well manured, it grows luxuriantly in the open air, and is extremely ornamental. It is much employed as food on the Continent of Europe and in America. It is extensively used in soups, stews, and pies, and is also sent to table boiled and served with toast and melted butter, or fried with butter, the last being by far the best mode of cooking it. The tender shoots and young leaves are boiled as greens or spinach, and the flowers and young shoots make an excellent dish fried. It is only beginning to be appreciated in Britain, though one variety, the *pompion*, or *pumpkin* (*C. Peto*, Linn.), has long been eaten in England by the poorer classes, generally mixed with apples and baked in a pie: it is sometimes boiled with milk; this is, however, the most insipid of the gourds. A great many ways of dressing the different varieties of pumpkins may be seen in the French and Italian books on cooking, and in the Gardener's Magazine, vols. vii. and viii. There are many other varieties cultivated in Europe, as the *Turban pumpkin;* the *melon pumpkin,* or *squash; American gourd,* or *Mammoth gourd,* which grows sometimes to the enormous weight of two hundred pounds, and used in Paris boiled to eat with meat as a substitute for potatoes and carrots. In many of the French provinces, where it is extensively cultivated, cows, hogs, and other cattle are fed upon gourds, and from the seeds large quantities of oil are expressed, which is used both for food and burning in lamps.

2536. *The botanical name* (*Cucurbita*) *is derived* from the resemblance which many species bear to certain vessels employed by chemists. In various parts of the world the shell is converted into bowls and other domestic utensils for holding water. The bottle gourd has a long neck and capacious ball, like a flagon.

2537. *Vegetable Marrow* (*C. ovifera*).—This is a variety of gourd which has been lately introduced into Britain, and is already cultivated to a considerable extent. It appears to have been brought to us from Persia by one of our East India ships. In shape it nearly resembles the cucumber, but is yellow when ripe, and attains the length of about nine inches. When young, it is excellent fried in butter; when half grown, it may be dressed in several ways, and has a peculiarly soft and rich flavour. It is also dressed plain boiled, and eaten with butter, or stewed in slices with rich sauce; and it is made into pies. The tender tops may be used as substitutes for greens.

Subsect. 3.—*Angelica* (*Archangelica,* Linn.).

2538. This herb is sometimes found native in Scotland, but is more abundant in the most northern parts of Europe, as Lapland and Iceland. The whole plant is powerfully aromatic. The seeds are employed to flavour ardent spirits or the choicest liquors; and in Sweden, Norway, and Lapland, the leaf-stalks are peeled and eaten raw as a great delicacy, or boiled with meat and fish. In England and France they are candied by the confectioner. The root, as well as the leaves and seeds, are employed for medicinal purposes, and in Lapland is chewed like tobacco.

Subsect. 4.—*Anise and Cummin* (*Pimpinella Anisum,* Linn.).

2539. The seeds of the anise, which is a native of Egypt, have been long used in this country, in confectionery and for distillation: they are imported from China, and Alicant, in Spain. Anise is somtimes cultivated in our gardens, and its leaves are used, like fennel, as a garnish and for seasoning.

2540. *Cummin* (*Cumminus,* Linn.).—The seeds are used in the north of Europe as a warm and stimulating spice in ragouts and other dishes, and are also put into liquors.

Subsect. 5.—*Coriander* (*Coriandrum Sativum,* Linn.).

2541. This plant, of eastern origin, has been long cultivated in England for its seeds, which are highly aromatic, and form one of the less agreeable spices: they are employed by the distiller in flavouring spirits, by the confectioner for incrusting with sugar, and by the druggist in medicine. Its tender leaves are also sometimes used in soups and salads, and in Peru the seeds are employed in great excess to season their food.

Subsect. 6.—*Caraway* (*Carum Carisi,* Linn.).

2542. The caraway is a native of this country, and is found growing in meadows. It is likewise cultivated for its seeds, large quantities of which are produced in Essex. The seeds have a pleasant aromatic odour, and a sweetish, warm, pungent taste, depending upon an essential oil, which is easily extracted by rectified spirit, and partly so by water. They are employed in confectionery, in cakes, biscuits, &c.; in medicine as a carminative, and for flavouring spirituous liquors; and the young leaves are sometimes used in soups: formerly the roots were eaten as parsnips, and by some are thought to be not inferior.

Subsect. 7.—*Rue and Hyssop* (*Ruta Graveolens,* Linn.).

2543. Rue is a hardy evergreen shrub, cultivated time out of mind in our gardens, but supposed to be originally a native of the south of Europe. It has a strong, ungrateful odour, and a bitter, hot, and penetrating taste. It is employed only for its medicinal qualities.

2544. *Hyssop* (*Hyssopus officinalis,* Linn.).—This, like the last, is only used in medicine; the leaves and young shoots rarely as a pot-herb.

Subsect. 8.—*Chamomile* (*Anthemis Nobilis,* Linn.).

2545. This very useful and generally-used aromatic bitter grows wild in England. It is cultivated on account of its flowers, an infusion of which forms an excellent stomachic, known by the name of *chamomile tea.* Though the double sort is most raised by gardeners, the single is the best and strongest as a medicine. The flowers are kept dried in bags. The active principle of chamomile is a resinous substance called *piperina,* discovered by Dr. A. T. Thomson.

SUBSECT. 9.—*Elicampane* (*Inula Helenium*, Linn.).

2546. This aromatic plant was formerly in great repute in England for its medicinal virtues, and was to be found in every physic garden. It is still cultivated, and the root is candied as a stomachic. It is found wild in moist pastures in the south of England.

SUBSECT. 10.—*Liquorice* (*Glycyrrhiza Glabra*).

2547. This medicinal plant is a native of the south of Europe, but has been cultivated in this country since 1562, chiefly for the use of brewers and distillers. The liquorice of the shops is the juice of the roots obtained by expression, decoction, and inspissation, and is manufactured only in Sicily and Spain; hence the name Spanish juice. It grows so abundantly in these countries and in Languedoc, that it is considered as a weed like the horseradish here, and is looked upon as a great nuisance to the cultivator. Its roots penetrate to a great depth, and are difficult to eradicate.

SUBSECT. 11.—*Wormwood* (*Aremisia Absinthium*, Linn.).

2548. The intense bitter of this plant is so great as to render it proverbial. Its odour is strong, and, though fragrant, yet to many persons it is disagreeable and nauseous. It grows wild in England, but is likewise cultivated for several purposes, though less used than formerly. It has tonic properties, and is sometimes employed as a stomachic. The French beverage or liqueur, called *eau d'absinthe*, thought to create an appetite, is prepared from wormwood, by the addition of alcohol and subsequent distillation. The active part seems to be the extractive, for the essential oil which it contains is not in the least bitter. Before the use of hops was known, wormwood was much employed in the composition of beer or ale: for this purpose it was gathered when in seed, and dried; some prefer its flavour to that of the hop.

SUBSECT. 12.—*Balm* (*Melissa Officinalis*, Linn.).

2549. Balm, formerly much employed in medicine, is still found to make a very grateful and useful drink in fevers. The herb, in its natural state, has a weak aromatic taste, and a pleasant smell, somewhat of the lemon kind. It was originally brought from the south of France. The leaves may be kept dried in the sun or oven, and preserved for use.

SECT. XIII.—PLANTS USED ONLY IN PRESERVES AND PICKLES.

2550. Many of the plants already described, as well as many foreign plants and fruits, are made into preserves and pickles. The following are a few that are not employed in any other way.

SUBSECT. 1.—*Caper* (*Capperis Spinosa*, Linn.).

2551. Capers, so much employed in sauces, are the unopened buds of a low trailing shrub or bush that grows wild like brambles in the fissures of rocks in Greece and the north of Africa, and is cultivated in the south of Europe. They are pickled in salt and vinegar, and come to us from Italy, Sicily, and the south of France; the best are from Toulon.

SUBSECT. 2.—*Samphire* (*Crithmum Maritimum*, Linn.).

2552. Samphire is a native of Britain, and is found growing on rocky cliffs by the sea, and in dry stone walls. The danger incurred by gathering it is described by Shakspeare in a well-known passage in King Lear. It is not easily cultivated, but is chiefly gathered in its wild state for pickling, and as an addition to salads. It is crisp and aromatic. *Golden samphire* and *marsh samphire* are varieties likewise found upon the seashore, or in salt marshes, and applied to the same use.

SUBSECT. 3.—*Tomato, or Love-apple* (*Solanum Lycopersicum*).

2553. This is a native of South America, and *Tomato* is the Portuguese name. The fruit is about the size of a small apple, contains a very agreeable acid, and is now much used in gravies, soups, and sauces. It is also served at table boiled or roasted, and sometimes fried with eggs. When green, it makes a good pickle and catchup, and is found in our vegetable markets; even in its unripe state it makes an excellent sauce, like apples or gooseberries, for roast pork or goose: when fully ripe, it makes an excellent store sauce.

2554. *The egg plant* (*Solanum esculentum*, Linn.) is allied to the last, and, though not uncommon in our green-houses, is seldom employed in this country as an article of cookery: it has less flavour than the love-apple; but it is more employed on the Continent, and in warmer latitudes, where its growth is attended with less trouble; it enters into stews and soups, and it is eaten as fritters, sliced and fried with oil or butter; it then forms a pleasant variety of esculent.

SECT. XIV.—POISONOUS PLANTS THAT GROW WILD IN BRITAIN.

2555. Every gardener should be acquainted with the following plants, that he may point them out, and enable such persons as are in search of edible wild plants to avoid them:

Chelidonium majus
Cicuta virosa.
Colchicum autumnale.
Œnanthe crocata.
The leaves of Prunus lauro-cerasus, though the berries are used in puddings.
Aconitum Napellus.
Aconitum lycoctonum
Actæa spicata.
Rhus toxicodendron.
Æthusa cynapium.
Atropa belladonna
Datura stramonium.
Hyoscyamus niger.
Solanum dulcamara
Solanum nigrum.
Lactuca virosa.
Apium graveolens
(The last two plants, in a cultivated state, afford lettuce and celery; but wild, in hedges and ditches, they are poisonous.)
Conium maculatum.
Digitalis purpurea.
Helleborus fetidus.
Juniperus Sabina.
Scrophularia aquatica
Asclepias Syriaca.
Bryonia dioica.
Euphorbia Lathyrus.
Euphorbia amygdaloides.
Mercurialis perennis.
Mercurialis annua.
Periploca Græca.
Veratrum album.

Professor Burnett observes that, lately, seventeen convicts at Woolwich were poisoned by eating the roots of Œnanthe crocata, which grows wild near Woolwich, and four of them died. Other similar instances are recorded in the Reports of the Medico-Botanical Society. A variety of Œnanthe, though dangerous when wild, is innocuous when improved by cultivation, and is eaten at Angers, in France.

Sect. XV.—esculent fungi

2556. *Fungus is the botanical name* for a very numerous tribe of plants, which are distinguished from other vegetables, not only by their singular forms, but by their chemical composition, yielding, upon analysis, not only the usual components of the vegetable kingdom, carbon, oxygen, and hydrogen, but likewise a large proportion of nitrogen, by which they approach more nearly to the nature of animal flesh. Dr. Darwin observed, long ago, that all the mushrooms cooked at our tables, as well as those used for catchup, possessed an animal flavour; and soup enriched by mushrooms only has sometimes been supposed to contain meat.

2557. *In this numerous tribe, a large proportion are poisonous*, a few are wholesome, and a vast number are still unknown as to their action upon the human constitution. The poisonous and wholesome species are often very similar; and as it is difficult to distinguish between many of them, even by botanical characters, the use of wild mushrooms is very unsafe. The few that it is customary to eat and to cultivate are known to those who are in the habit of collecting them, and no one should venture upon eating a species they do not understand. It is a remarkable circumstance that certain species that are eaten as food in one country are rejected as poisonous in another, which seems to show that their deleterious properties are owing to climate, situation, or accidental circumstances, rather than any specific peculiarity. In some parts of Europe, as Russia, Poland, and parts of Germany, there are above thirty species growing wild that are used as food, and cooked or preserved in various ways, whereas in Britain only two are generally eaten.

2558. *The garden, or cultivated mushroom* (*Agaricus campestris*, Linn.).—This species, which is considered as the best, and is the most usually eaten in England, is cultivated in gardens; but it is also found abundantly springing up wild in rich open pastures. It is distinguished from the poisonous kinds called *toad stools* by its having pink or flesh-coloured gills or under side, and by its invariably having an agreeable smell. When young they are of a roundish form like a button, the stalk as well as the button being white, and the fleshy part being very white when broken, the gills within being livid. As they grow larger, they expand their heads by degrees into a flat form, and the gills underneath are at first of a pale flesh-colour, but as they stand long become blackish or brown. The poisonous kinds are mostly all brown, and generally have a rank, putrid smell. The edible mushrooms seldom grow in woods, but many of the poisonous sorts are to be found there. Mushrooms are stewed or boiled, and are employed in flavouring many dishes. They are also pickled and dried, and when reduced to powder, and kept in this state in close bottles, they are very useful in the season when they do not grow. The wild mushrooms of the same species are considered superior in point of flavour to those raised in the garden; but the latter are safer on account of the risk of gathering improper sorts. *Catsup*, or *catchup*, is made from mushrooms by mixing salt and spices with their juice. The young, when globular, called *buttons*, are best for pickling.

2559. *A. pratensis* is a much esteemed species, known by the name of *champignon:* the best grow in parks and dry pastures, where the turf has not been ploughed up for many years; they have a finer flavour than the garden mushroom; the gills are cream-coloured. These are much employed for catchup and in stews; but it is said that they are apt to be hard and leathery, in which state they are indigestible, and they are so like some poisonous kinds that they should be gathered with caution.

Besides these, however, there are several edible mushrooms in this country; and in particular districts, where the inhabitants are well acquainted with them, they are used; but, as we have before stated that there are many which are poisonous, we would advise those who are not very conversant with their characters to abstain from gathering them.

Mushrooms vary much in size: some are only an inch or two in diameter, others have been known to measure eight or ten inches across. Dr. Withering mentions a species on the seacoast of Cornwall which has the cap eighteen inches in diameter, and the stem as thick as a man's wrist; and one was gathered in a hot-bed in Birmingham that weighed fourteen pounds.

The manner of propagating the fungus tribe is remarkable and peculiar, and the properties of some of those which are found in other parts of the world are extraordinary. Besides those which are powerful poisons, some are medicinal; and one species in the northeast part of Asia is employed to produce intoxication.

All mushrooms require to be very well cooked, particularly those which are large.

CHAPTER IX.

DESCRIPTION OF THE FRUITS USED AS FOOD IN BRITAIN.

SECT. I.—GENERAL OBSERVATIONS.

2560. The most agreeable, if not the most useful, species of vegetable food consists of fruits. The hardy fruits, or such as grow without the aid of artificial heat, are valuable as food, independently of their employment in the dessert; and some of these, as the apple and the gooseberry, &c., are easily within the reach of the humbler classes.

2561. *The most important of our fruits were originally the produce of warm countries*, and have, by the art of cultivation, been gradually acclimated to temperate regions. Those enlightened nations of antiquity, the Greeks and Romans, introduced into Italy many fruits from countries which they subdued, and it was their constant practice to extend these advantages to their conquests. In this manner the fig, the orange, the peach, plum, cherry, apple, and pear, almonds, olives, and a great variety of others, mostly natives of Asia, have been spread over Europe; and thus war, productive of so many evils, has, in the early stages of society, contributed to diffuse the arts of civilization. Before the invasion of the Romans, Britain probably possessed no other than the wild fruits of Northern Europe, the crab, the sloe, the hazelnut, and the acorn. Much was due to the Anglo-Saxon monks, who, in their time, were probably the only gardeners, and who bestowed much care in the cultivation and improvement of some of our best fruits; their vineyards and orchards were in great perfection from the twelfth to the fifteenth century.

2562. *The Crusades*, unjust as they were, contributed to the improvement of European society; and the monastic gardens owed some of their choicest fruits to the ecclesiastics who had accompanied the expeditions to the Holy Land. In the same manner, the Spaniards introduced the European vegetables and fruits into America, as the English missionaries are now doing in the islands of the Pacific, and in Africa.

2563. *The discovery of the New World*, and the extension of commerce in the reign of Queen Elizabeth, added considerably to the number of our fruits and vegetables; and this princess herself set an example as a horticulturist. Under the Stuart family, gardening was greatly improved; and in each succeeding reign it made a steady progress.

2564. *At present* every part of the globe is examined by our botanists, and constant additions are being made to our knowledge of the vegetable kingdom. The modern improvements in science, and the art of gardening, have enabled us to add to our list numerous tropical plants, some of which, though at their first introduction they were kept entirely in stoves, are now planted out, and can bear the rigour of our ordinary winters; from which it may reasonably be expected that they may be so far acclimated here as to ripen in the open air. Already we find pineapples and melons, formerly so rare, now by no means uncommon in Covent Garden market, and sold at very moderate prices.

2565. *On this subject Sir Joseph Banks has observed:* "It does not require the gift of prophecy to foretell that ere long the aker and the avocado pear of the West Indies, the flat peach, the mandarin orange, and the litchi of China, the mango, the mangostan, and the durion of the East Indies, and possibly other valuable tropical fruits, will be frequent at the tables of opulent persons; and some of them, perhaps in less than half a century, be offered for sale every market-day in Covent Garden."

2566. *The extended introduction of inter-tropical fruits* begins much to interest the admirers of these natural productions, and trials may be made without much additional expense in our hot-houses, now fitted up in such perfection. The banana, or plantain, has been fruited in Britain nearly forty years ago, and frequently since. When the hothouse is lofty enough, it is a magnificent plant, and makes an appearance even surpassing what it exhibits in its native country, where its ample leaves are often torn in pieces by the winds. The mango has been also fruited, both in France and England; and if some of the best varieties were imported with care from Jamaica, there is little doubt that, with proper cultivation, they might be had on the table as easily as the pineapple.

But the orange trade displays in a singular manner the advantages which we derive from the present commercial system. Though these are fruits of climates much warmer than ours, yet we obtain them at a price little higher than that of our domestic fruits. Nor should we forget, while on this subject, that some of our wild fruits, as the berries, perhaps deserve to be made the subject of experiment how far they may be capable of improvement, and whether it may not be judicious to attempt their melioration.

2567. *Great advantage has been derived of late to the cultivation of fruits in general by the establishment of horticultural societies*, particularly the London and Caledonian, the

"Transactions" of which contain much valuable information on this interesting subject: great pains have been bestowed to select and disseminate the best varieties.

2568. *The fruits which we propose to describe* we shall divide, with Mr. Loudon, into,

1. *Kernel fruits*, or *pomes:* those having the seeds enclosed in membranous cells, including the apple, pear, quince, and medlar. These are also called fleshy fruits.
2. *Stone fruits:* having the seeds enclosed in hard nuts covered with flesh, or a sarcocarp, as the peach, nectarine, almond, apricot, plum, cherry, and olive.
3. *Pulpy fruits:* having the seeds lying among the pulp, as the pineapple, grape, melon, cucumber, fig, and tamarind.
4. *The orange tribe:* this contains a well-known group, the sweet orange, the bitter orange, lemon, citron, and shaddock.
5. *Berries:* a smaller kind of pulpy fruits, as the gooseberry, current, raspberry, strawberry, mulberry, elderberry, barberry, whortleberry, cranberry, blaeberry, blackberry, dewberry, juniper berry, and service berry.
6. *Exotic fruits:* occasionally imported, or but little known in England, as the pomegranate, plantain, banana, mango, mangostan, aker, bread-fruit, durion, guava, litchi, jujube, juvia, alligator, or avocado pear, anchovy pear, custard apple, and papaw.

2569. *No class of substances employed as food varies more in their dietetic qualities than fruits*, which, though extremely salubrious when used judiciously, are frequently injurious, particularly to the invalid. It is essential, in order to have a just view of this subject, to discriminate accurately between different species, the state of ripeness, the time and circumstances under which fruit is eaten, as well as the constitution of the consumer. There are three modes in which fruits may be used as food: in a crude state, dried, or prepared by the art of cookery. A very great change takes place as they advance towards maturity from the unripe state. In the latter, in general, acids and astringent matter abound, which is often converted into sugar when they ripen; hence the injurious properties of many unripe fruits which are perfectly wholesome when ripe. Similar changes in their constituent principles frequently take place during the operation of cooking; as, for instance, a portion of the acid of apples becomes sugar; and, in general, numerous fruits, very indigestible in their raw state, when boiled, roasted, or stewed, form excellent food. The acid of unripe fruits is usually objectionable, but that of fruits in their ripe state is often cooling and salutary, when sufficiently diluted. Those which, when ripe, have about an equal mixture of acid and sugar, as the strawberry, raspberry, grape, and orange, are particularly agreeable and wholesome in the warm part of the year, when they are in the most perfect condition. Of our natural fruits, the cherry and the nut tribe are the least wholesome.

2570. The drying of some fruits, as raisins, not only enables the inhabitants of cold countries, through the medium of commerce, to enjoy a species of food which their climate has not permitted them to cultivate, but, by this process, the watery and acid juices being in a great measure dissipated, they become less disposed to ferment in the stomach, and are, in general, safer than in a crude state.

2571. *With respect to the chemical analysis of fruits*, the small progress that has been made in the very difficult branch of vegetable chemistry precludes the possibility of giving the composition of all of them, very few having been subjected to rigid investigation. Many of them contain peculiar principles, and, in general, their composition is complicated. The usual principles in fruits are water, sugar, bitartrate of potash and of lime, malic acid, acetic acid, citric acid, binoxalate of potash, vegetable mucilage or extractive matter, tannin, the principle of flavour, and the colouring principle. The sugar of fruits is generally of the uncrystallizable kinds. The acids are chiefly the malic, acetic, and citric. In a few these are found free, but are most frequently combined with lime or potash. Malic acid is found in apples, currents, gooseberries, strawberries, raspberries, elderberries, and plums. Several acids are frequently found in one fruit.

Sect. II.—Kernel Fruits.

2572. These, *called also pomes*, from the Latin word signifying apple, have a pulp rather firm, so as to be termed fleshy by botanists, and they have their seeds not loose in the pulp, nor enclosed in a hard shell, but contained in cells formed of tough membranes.

Subsect. 1.—*Apple* (*Pyrus Malus*, Linn.).

2573. *No fruit in Britain is so abundant, and so generally useful, as the apple*, and none can be brought to such high perfection with so little trouble. It is employed at the dessert, in the kitchen, and for making cider. It is important from its hardiness and excellent flavour; and it has this striking advantage over all our other fruits, that it remains longest in season, and may be preserved with ease through the winter; whereas our stone fruits can only be kept in their natural state for a few days, and require extraordinary means to preserve them.

2574. *Homer describes the apple as one of the precious fruits of his time*, and it was cultivated and highly esteemed among the Romans, who brought it from the East, and set an extraordinary price upon fine bearing trees. The best varieties are natives of Asia, and have been introduced into Europe by grafting upon others. The only variety indigenous to Britain is the austere crab-apple of our hedges; but the cultivated kinds were introduced at an early period. During the Saxon heptarchy, Somersetshire and Devonshire were called the apple country, and there were large plantations near Glastonbury. Some apple-trees in Herefordshire now existing are said to be a thousand years old, and many varieties were undoubtedly brought over by the Normans in the time of William the Conqueror. The varieties of the apple have been prodigiously increased in this country, this fruit having a peculiar tendency to change by circumstances connected with its cultivation. Parkinson, in 1629, enumerates fifty-seven sorts. Evelyn, about thirty years afterward, states that "it was through the plain industry of one Harris, a fruiterer to Henry VIII., that the fields and environs of about thirty towns in Kent only were planted with fruit from Flanders, to the universal benefit and general improvement of the county." Hartlet, in 1650, speaks of "one who had 200 sorts of apples," and "verily believes there are nearly 500 sorts in this island." Since that time there has been a continual accession of sorts received from the Continent, as well as numerous varieties raised from seeds. The last catalogue of fruits, published by the Horticultural Society of London in 1831, enumerates 1400 sorts of apples, and those which have been acquired since that time would extend the list to 1500. Of no other fruits are there so many excellent varieties in general cultivation, suited to almost every soil which our island affords. Some sorts are ripe in the beginning of July; others ripen much later: those which ripen latest are the best.

2575. *Apple-trees will not grow in tropical countries*, but, like the oak, extend from the tropics to the latitude of 60°, and are not to be found in Lapland. The apple is, therefore, the growth of temperate and rather cold climates only.

It has been supposed, and the opinion was supported by Mr. Knight, that many of the oldest varieties of apples known to our ancestors are worn out, and others are now in a state of debility; thus the celebrated golden pippin, which was formerly the common cider apple of the Hereford orchards, is now preserved with difficulty in our gardens. This opinion, however, has been controverted.

Apples are divided into those which, from sweetness, are fit for eating, called *eating*, or *table apples;* those which are proper for pies, tarts, &c., termed *kitchen* or *baking* apples; and those for making cider, or *cider* apples. The best baking apples are the Colvilles, for early use; the rennets and pearmains, for autumn; the russets, and Padley's pippins, for winter and spring. For dessert apples, Margarets, for early use; Pomeroy, summer pearmain, and Kentish codlin, for summer use; golden, Dowton, and other pippins, especially the ribstone, with the nonpareil, and other small russets, for autumn, winter, and spring. Some apples are not eatable until kept some time.

2576. *All apples contain* sugar, malic acid, or the acid of apples, mucilage or gum, woody fibre, and water, together with some aroma, on which their peculiar flavour depends; and their different qualities may be traced to the different proportions of their principles. The hard, acid kinds are unwholesome if eaten raw; but by the process of cooking, a great deal of this acid is decomposed, and converted into sugar. The sweet and mellow kinds form a valuable addition to the dessert, and they are employed in the composition of marmalades, jellies, &c.; and from the juice is prepared a drink useful in fevers. A great part of the acid juice of the apple is converted into sugar as the fruit ripens, and even after it is gathered, by a natural process termed maturation, an account of which is given in the article "Preservation of Fruit." On the contrary, when apples decay, the sugar is changed into a bitter principle, and the mucilage becomes mouldy and offensive.

As in apples more than half consists of water, and as the rest of the ingredients are not of the most nutritive kind, this fruit cannot rank high as food; it is chiefly useful as an agreeable acid-sweet summer fruit. When cooked it is considered as slightly laxative, and therefore a useful adjunct to other food: this is probably the origin of apple sauce, so common with pork, ducks, and goose. The raw fruit is not advisable for dyspeptic persons. Old cheese has a remarkable effect in meliorating them when eaten; probably from the volatile alkali or ammonia of the cheese neutralizing their acid.

SUBSECT. 2.—*Pear (Pyrus Communis,* Linn.).

2577. The pear, like the apple, is indigenous to this country; but the wild pear is a very austere fruit. The best varieties were brought from the East by the Romans, who cultivated them with care, and probably introduced some of their best sorts into this island, to which others were added by the inhabitants of monasteries. The Dutch and Flemings, as well as the French, have excelled in the cultivation of the pear, and most of the late varieties introduced by the Horticultural Society are from France and Flanders.

The pear is a hardy tree, and a longer liver even than the apple; in a dry soil it exists for centuries. It will grow in almost any soil, and flourishes perfectly in our hedges.

2578. *Eating pears* were formerly divided into two sorts, viz., *proud pears*, which would not keep, and *woodens*, so called from their property of keeping. Pears however, have been wonderfully improved as a table fruit within the last twenty or thirty years, through French and Flemish botanists and horticulturists, by whose experiments our own gardeners have largely profited. The best sorts are delicious, and are preferred to the apple at the dessert. They should have a rich aromatic flavour, and be either of the melting kind (*buerré*, butter pears), or be firm and crisp, like the winter bergamots.

2579. *Above* 150 *varieties of pears are enumerated in late catalogues*, all differing from each other in their qualities, time of ripening, &c. For summer pears, some of the best are the Muscadelle, Windsor, Jargonelle, Bonchrêtein, &c. For winter, the St. Germain, Wilding, Rousselet, Bergamot, &c. For the kitchen, the Swan's Egg, Spanish red wooden, black Worcester, &c. Perhaps one of the most delicious sorts in Europe is that known throughout the north of Spain as the Pera de Mantiga, or "Butter Pear," and some of a very superior kind are grown in Guernsey and Jersey. The species grown in the neighbourhood of Guimaræns, in the north of Portugal, is equally celebrated.

2580. *Though perfectly wholesome when ripe, the pear is not so when green;* but in this state it is fit for stewing. The best kitchen pears for baking are rather austere than sweet: cooking converts part of the acid into sugar. They may be preserved in the same way as apples; but they are also pared and dried in an oven, by which means they will keep for years: this mode is much practised in France.

This fruit is likewise much employed for making perry, and the most austere varieties, unfit for eating, are best for this purpose. A mixture of the wild pear with the cultivated sort is thought to make peculiarly fine liquor.

2581. We do not find any good analysis of the pear, but it is evidently not very different in its composition from the apple, in some varieties containing more sugar.

Subsect. 3.—*Quince* (*Pyrus Cidonia*, Linn.).

2582. This tree is classed by botanists with the apple and pear, and the latter are generally grafted on quince stocks, proving their consanguinity. It is a native of Austria, and grows wild on the banks of the Danube. It is said to have been introduced here from the Isle of Candia, and grows easily in our hedges, but is not much used, the fruit, in its raw state, having a peculiar disagreeable smell and an austere taste. It is sometimes employed to give a flavour to apples in pies and tarts, and is occasionally made into a marmalade, which is much used in the south of France, where the quince is extensively cultivated. The juice, as a medicine, is cooling, astringent, and stomachic.

Subsect. 4.—*Medlar* (*Mespilus Germanica*, Linn.).

2583. This fruit, a native of the south of Europe, but long naturalized, somewhat resembles a small apple, and has a good deal of flavour, but which is seldom developed, even in its ripe state, on the tree. It is gathered and laid by till it begins to change or grow rotten, when only it is fit to be eaten.

Sect. III.—stone fruits.

2584. *Stone fruits are such as have their seeds enclosed in a hard nut or shell, and this covered by a fleshy pulp.* Those which are known among us belong to the natural order of *amygdaleæ*, and consist of the peach, nectarine, apricot, plum, and cherry. All these contain certain principles in their kernels, from which Prussic acid is developed by the action of water, though this acid does not exist in them ready formed. Some species of this tribe in other countries are highly poisonous: the Cerasus capricida kills the goats of Nepal which happen to eat them; and the Cerasus Virginia of North America is known to be dangerous. Notwithstanding, however, this poisonous principle in the kernels, the pulp of our fruits of this kind are perfectly harmless.

Subsect. 1.—*Peach and Nectarine* (*Amygdalus Persica*, Linn.).

2585. These, which are among the most delicious of our fruits, are considered as varieties of the same species produced by cultivation. The latter is characterized by a very delicate down, while the former is smooth; but as a proof of their identity as to species, trees have born peaches in one part and nectarines in another; and even a single fruit has had down on one side, and the other smooth. The trees are almost exactly alike, as well as the blossoms.

2586. Pliny states that the peach was originally brought from Persia, where it grows naturally, from which the name of Persica was bestowed upon it by the Romans; and some modern botanists apply this as the generic name, separating them from the Amygdalus, or almond, to which Linnæus had united them.

2587. Although they are not tropical, they require a great deal of warmth to bring them to perfection; hence they seldom ripen in this country in ordinary seasons without the use of walls or glass; consequently, they bear a high price.

2588. In a good peach, the flesh is firm, the skin thin, of a deep bright colour next the sun, and of a yellowish green next to the wall: the pulp is yellowish, full of highly flavoured juice, the fleshy part thick, and the stone small. Too much down is a sign of inferior quality. This fruit is much used at the dessert, and makes a delicious preserve.

2589. Both the peach and the nectarine are separated into, 1, the *free-stone*, or *melting peaches*, those in which the pulp or flesh separates easily from the stone; and, 2, the *cling-stone varieties*, in which the flesh clings or adheres to the stone; the first are generally the best flavoured. There are above two hundred varieties enumerated in the catalogue of the Horticultural Society.

2590. Peaches are often cultivated in large quantities. At Montreuil, a village near Paris, almost the whole population is employed in the growing of peaches, which has maintained the inhabitants for ages; and the consequence is, that they raise better peaches there than in any other parts of France. The best in Europe are Italian. In Maryland and Virginia, peaches grow nearly wild in extensive plantations or orchards resembling forests, but the fruit is of little value for the table, being employed only in fattening hogs, and for the distillation of peach brandy. On the east side of the Andes, peaches grow wild among the cornfields, and in the mountains, and are dried as an article of food.

2591. The young leaves of the peach are sometimes used in cookery from their agreeable flavour; and a liqueur resembling the fine noyeau of Martinique may be made by steeping them in brandy sweetened with sugar and fined with milk: gin may also be flavoured in a similar manner. The kernels of the fruit have the same flavour.

2592. *The nectarine is said to have received its name* from nectar, the particular drink of the gods. Though it is considered as the same species as the peach, it is not known which of the varieties came from the other: the nectarine is by some considered as the superior fruit.

SUBSECT. 2.—*Almond (Amygdalus).*

2593. *The almond-tree is a native* of warmer climates than Britain, and is indigenous to the northern parts of Africa and Asia; but it is now commonly cultivated in Italy, Spain, and the south of France. It is not usually grown in Britain, and the fruit seldom ripens in this country; it is much admired for the beauty of its blossoms. It strongly resembles the peach tree in the form of its leaves and blossoms, and is included in the same genus by botanists; but the fruit, instead of presenting a delicious pulp like the peach, shrivels up as it ripens, and becomes only a tough coriaceous covering to the stone enclosing the eatable kernel, which is surrounded by a thin bitter skin. It flowers early in the spring, and produces fruit in August.

2594. *There are two sorts of almonds, sweet and bitter*, but they are considered to be only varieties of the species; and though the qualities of the kernels are very different, they are not distinguishable by their appearance.

2595. *The sweet almond* (*A. communis*, Linn.) is much used at the dessert and in confectionery. The Valentia almond is sweet, large, and flat-pointed at one extremity, and compressed in the middle. The Italian almonds are not so sweet, smaller, and less depressed in the middle. The Syrian or Jordan almonds come from Malaga, and are the best sweet almonds brought to England. They are longer, flatter, less pointed at one end, and less round at the other, and have a paler cuticle than those just mentioned. Almonds are not considered to be very digestible. The brown skin easily comes off by pressing with the fingers when they are put into boiling water: they are then dried till they are brittle, and the interior part being white, they are then said to be *blanched*. This skin, or pellicle, sometimes disagrees with the stomach, and, on that account, almonds, when brought on the table as dessert, ought to be blanched.

2596. *When analyzed*, 91 parts of sweet almonds are found to consist of 54 parts of fixed oil, 3 of gum, 24 vegetable albumen, 6 saccharine matter, 4 woody fibre, 3 of water, and a trace of acetic acid.

2597. *The bitter almond* (*A. amarus*, Linn.) has, like the sweet, no smell when entire, but when bruised in a mortar it has the odour of the peach-blossom, and the taste is the pleasant one of the peach kernel, a property which occasions its use in flavouring many preparations.

2598. *Though bitter almonds do not contain prussic acid ready formed*, they contain two principles, amygdalin and emulsin, which, when acting on each other by means of water during distillation, produce prussic acid and a volatile oil, both violent poisons; and when bitter almonds are chewed, the moisture of the mouth and the emulsin of the seeds effect the decomposition of the amygdalin, and the consequent formation of prussic acid and volatile oil. Though the proportion of these poisons in a few of the almonds does not prove fatal, yet, when almonds have been eaten in large quantities, serious, and even fatal consequences, have been the result.

2599. *The volatile oil of bitter almonds* is sold in some shops under the name of *essence of bitter almonds*; and this is a most potent poison, being in general four times as powerful as the prussic acid kept in chemist's shops. A single drop of it will kill a cat in a few minutes. This preparation is sold to dealers in cordials, to make what they call "genuine noyeau," and it is used by some confectioners to flavour their preparations; but it is evident that so dangerous a substance should not be trusted in the hands of persons not thoroughly acquainted with its deleterious effects. See "Prussic Acid," Book VII., Chap. VII., Sect. 16.

2600. *Almonds contain a large proportion of fixed oil,* which is obtained by expression; his is mild and wholesome, and is much used in medicine as a pure oil. When almonds and water, with a little sugar, are triturated together in a mortar, a white liquor results, which is considered to be very nearly similar to animal milk, and is called *milk of almonds;* it is curdled by acids. Cream even separates from this milk, which may be converted into a species of butter. Several substances not mixible of themselves with water may, by trituration with almonds, be mixed with it, and thus fitted for medicinal use; such mixtures are called *emulsions.* Almond oil is used for making fine soap; and the almond cake, after pressing out the oil, is employed as a cosmetic.

Both sweet and bitter almonds contain the bland fixed oil obtained by expression, but it is chiefly procured from bitter almonds, which, after being blanched, are submitted to great pressure between two hot iron plates; the matter which remains, or the almond cake, is the source of the prussic acid, which is obtained by a subsequent process. When the cake is moistened with boiling water, the odour of the volatile oil, and of prussic acid, is immediately perceived.

2601. *The importation of almonds* into England amounts annually to about six hundred tons, of which about ninety-five are Jordan, the rest chiefly from Barbary and Spain. Bitter almonds come chiefly from Magadore.

SUBSECT. 3.—*Apricot* (*Prunus Armeniaca,* Linn.).

2602. *The genus Prunus includes the apricot, plum,* and *sloe.* The apricot was cultivated by the Romans, and is stated by Pliny to have been brought from Armenia, where it is found abundantly on the slopes of the mountains. Vast quantities grow in the oases of Africa, and are carried in a dried state to Egypt. It is the opinion of Mr. Royle, author of the "Botany of the Himalaya," that the Cabul Mountains are the source of the apricot, as well as many others of our fruit-trees. He states that the apricot grows wild at present in the hills between the Ganges and Jumna, as well as in Cashmere, together with the peach, nectarine, walnut, almond, plum, cherry, and also the apple, pear, quince, and pomegranate. It is also planted very abundantly round the villages, the fruit being eaten both fresh and dried, while a fine oil is expressed from the kernels. It is likewise plentiful in China and Japan.

2603. In the climate of England it is of less importance than many other fruits; its blossoms, in early seasons, are very subject to the effect of spring frosts, which renders its crops precarious. It is, however, much cultivated, and is used at the dessert, though inferior to the peach. The young fruit makes an excellent tart and preserve or jam, which is the use to which the apricot is best suited, possessing a moderate degree of acidity with a rich saccharine quality. The apricots produced upon standards, which are the best, do not appear north of Ipswich, and several of the sorts known in the south of Europe are too tender for England. It was first brought to this country by the gardener of Henry VIII.

SUBSECT. 4.—*Plum* (*Prunus Domestica,* Linn.).

2604. *The wild sloe is considered by Mr. Knight as the parent of the plum,* but the acclimated kinds come from the East. The cultivation of this fruit was probably attended to very early in England, as Gerard informs us that in 1597 he had in his garden in Holborn three score sorts.

2605. *The damson,* or Damascene plum, takes its name from Damascus, where it grows in great quantities, and from whence it was brought into Italy about 114 years B.C. The *Orleans plum* is from France. The *green gage* is called after the Gage family, who first brought it to England from the monastery of the Chartreuse, at Paris, where it still bears the name of *Reine Claude.* The *magnum bonum* is our largest plum, and greatly esteemed for preserves and culinary purposes. The best sorts of plums are agreeable at the dessert, and, when perfectly ripe, are wholesome; but some are too astringent. They lose much of their bad qualities by baking; and are extensively used, from their cheapness, in tarts and preserves, but they are not a very wholesome fruit, and should be eaten in moderation.

Dried plums are called prunes, of which several kinds are met with in the shops, and used at the dessert: the Brignolle plums, brought from Brignolle, in Provence, which is of a reddish-yellow colour, and has a grateful, sweet sub-acid taste; the common French prune, and the Damascene plum. Others come from the banks of the Rhine, by way of Holland, and others, again, are brought from Portugal. The *common medicinal prune* comes chiefly from Bordeaux.

2606. *The sloe* is a shrub common in our hedgerows, and belongs to the natural order Amygdaleæ. The fruit is about the size of a large pea, of a black colour, and covered with a bloom of a bright blue; it is one of the few indigenous to our island. The juice is extremely sharp and astringent, and was formerly employed as a medicine, where an astringent was necessary; it is employed in the manufacture of a red wine made to imitate port, and also for adulteration. The leaves have been employed to sophisticate tea. The fruit, when ripe, makes a good preserve.

2607. *The bird cherry* (*Prunus Padus,* Linn.) is a fruit little known, and nauseous to most palates, but when infused in gin or whiskey, it greatly improves these spirits, and the infusion is only surpassed by that of peach leaves.

SUBSECT. 5.—*Cherry* (*Cerasus Duracina*, Linn.).

2608. It is a question whether this beautiful fruit be indigenous in Britain. It is generally stated that the cherry was brought to Italy by the Roman general Lucullus from a town in Asia called Cerasus, and that we owe it to the Romans. This may be true of some varieties, but the cherry appears to be a native of most temperate countries of the northern hemisphere, and a small black wild cherry is found in Herefordshire, and even in the mountains of Scotland; this, when cultivated in Aberdeenshire, where it is known by the name of *Geans*, is a delicious fruit. At some of the ruins of our abbeys and baronial castles there are still existing some of these black cherry-trees that have attained the height of sixty or eighty feet, and which now produce vast quantities of fruit. All agree that the cherry has been a favourite fruit in England, and in general cultivation ever since the time of Henry VIII., when it was planted in Kent, where cherry orchards were formerly very extensive, and are still celebrated; but this fruit was probably introduced here at a much earlier period, for it is ascertained that in the fifteenth century it was hawked about the streets of London in the same manner as at present.

2609. *About two hundred varieties of cherries are enumerated*, some of which are in season, from the Kentish and May duke at the beginning of autumn, to the yellow Spanish and Morillo late in the winter. When perfectly ripe they are refreshing, and are excellent for pies and tarts. *A wine is made from the juice* resembling red Constantia. *A spirit is also distilled* on the Continent from the pulp fermented, called *Kirschevasser*. The liquor called *cherry brandy* is made by putting the best black varieties into brandy. *Noyeau* is a liquor flavoured by the kernels of the variety *Cerasus occidentalis*; and a large black cherry is employed in the *ratafia* of Grenoble. The *maraschino* of Zara is made from a particular species cultivated in Dalmatia.

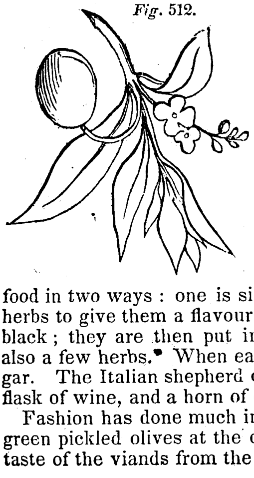
2610. *The cherry is, by some botanists, included in the same genus as the plum* (*Prunus*), and, like all this class of stone fruits, contains in its leaves and kernels some of the principles which are the source of the agreeable flavour resembling that of the peach-blossom. The poisonous liquid called *laurel water* is made by distilling the leaves of the *bird cherry*; those of the *Lauro-cerasus*, or cherry-laurel, as well as some other cherry leaves, afford a similar liquid, although the fruits are not poisonous.

SUBSECT. 6.—*Olive* (*Olea Europæa*, Linn.).

2611. The olive-tree is interesting from historical recollections. It was the leaf of this tree, brought into the ark by the dove, that gave the first evidence of the waters of the deluge having abated, since which time it has been employed as an emblem of peace. The olive was sacred to Minerva; it frequently appears in Grecian sculpture, and a wreath made of the leaves was a reward bestowed in the games of Athens. The mention in Scripture of the Mount of Olives near to Jerusalem proves it to have been a favourite tree in Palestine; and it is an interesting fact that wild olives still exist upon the spot. The olive is indigenous in Syria, Greece, and the north of Africa; and the beautiful plain of Athens seems almost covered with them.

2612. *The cultivated olive* (*fig.* 512) was introduced into Italy by the Romans: it now grows there in great abundance, as likewise in Spain and the south of France, but the fruit will not ripen in countries farther to the north. It will grow in England, but though an evergreen in warmer climates, with us it loses its leaves in winter, and the fruit does not ripen in the open air.

Fig. 512.



2613. *The fruit* is smooth and oval, about three quarters of an inch in length, and half an inch in diameter, being about the size of a small plum. When ripe it is of a deep violet colour, whitish and fleshy within; it is rather bitter, and to many nauseous, but has its pulp replete with a bland oil, and with an oblong, pointed, rough nut in the interior. In Greece, and also in Portugal, the fruit is eaten in its ripe state, but its taste is not agreeable. They are prepared for food in two ways: one is simply to cut and soak them in salt and water, adding a few herbs to give them a flavour; the other is to dry them in the sun, whereby they become black; they are then put into jars, with oil, salt, and pepper, or other spices, adding also a few herbs. When eaten, they are invariably flavoured with oil and a little vinegar. The Italian shepherd often takes nothing to the field with him but a little bread, a flask of wine, and a horn of olives; indeed, bread and olives form a nutritive diet.

Fashion has done much in this country to introduce and create an acquired taste for green pickled olives at the dessert. They are chiefly taken with a view to remove the taste of the viands from the mouth, previously to enjoying the flavour of wine.

Three kinds of olives come to London, Italian, French, and Spanish. The former are the best, and are from Lucca; the French are from Provence, and are also excellent; the Spanish are larger, but more bitter.

2614. *Olives are pickled in the following manner:* being gathered before they are ripe, they are suffered to steep in water for some days, and afterward are put into a lye of water and barilla, with the ashes of olive stones calcined, or with lime; and after remaining there a sufficient time, are bottled or barrelled with salt and water. They are thought to promote digestion and give appetite.

2615. *But olives are chiefly cultivated for the oil which they produce,* and which, in the countries where they grow, forms as necessary an article in the culinary art as butter with us. Olive oil, called also *salad oil,* is also largely used in Britain for the more delicate parts of our cookery, instead of butter, and is a useful addition to salads, preventing them from running into fermentation and producing flatulency. When the fruit is ripe, it is put into a bag of rushes, and the oil is forced out by gentle pressure. The first affords the virgin or best oil; a second quality is procured by a pressure sufficient to break the kernels. After the oil has been drawn, it deposites mucilage, and, when sufficiently clear, it is put into clean flasks, as we receive it. The greatest part of our best oil comes from Italy, and is known by the name of Florence, Lucca, and Gallipoli oil. Some is also brought from Spain and the Grecian islands. When quite fresh and pure, it has very little taste or smell, and is quite transparent, having only a pale greenish tint. It is sometimes adulterated with poppy oil.

SECT. IV.—ORANGE TRIBE.

2616. To the orange tribe or genus (*Citrus*) belong the *sweet orange*, the *Seville*, or *bitter orange*, the *lemon*, the *citron*, the *lime*, and the *shaddock*. They are all remarkable for containing much *citric acid* in their juice, and a very odoriferous and inflammable, acrid, essential oil in their outer rind. Besides these principles, they also contain the malic acid, and more or less of the saccharine and bitter principles. In the orange the sugar is prevalent, but in the Seville orange the bitter principle prevails.

The acid varieties are much used in medicine, and in the manufacture of cooling drinks; the sweet varieties are esteemed for the dessert, and the bitter as stomachics. The rind affords the essential oil of lemon and bergamot; and from the flowers a fragrant aromatic water is distilled. The unripe, or abortive fruits, called Curaçoa oranges, are used to flavour the delicious liqueur called *Curaçoa.* They are natives of the warmer parts of Asia, though they have been long introduced into the West Indies, the tropical parts of America, the Atlantic isles, and the warmer parts of Europe.

SUBSECT. 1.—*Sweet Orange* (*Citrus Aurantium*).

2617. This very useful and agreeable fruit gives us a striking instance of the advantages of commerce. Although the production only of countries much warmer than our own, we enjoy it nearly at the price of our ordinary fruits; and this is the more important, since it is perhaps the most refreshing and healthy of all fruits of warm countries. It is calculated that about 27,000,000 oranges are annually imported into England, and they are brought without any preparation farther than wrapping each separately in paper, and packing them in boxes.

Most of the oranges and lemons intended for exportation are gathered before they are quite ripe, for if they were mature, they would spoil in the carriage. The gathering of them for the British market usually occupies from the beginning of October to the end of December. They are not ripe till the spring. Though the name of China is attached to it, it is doubtful whether it was originally a Chinese fruit; and it has been supposed by some classical commentators that the golden apples of the Hesperides were the orange.

2618. *The best come from St. Michael's,* in the Azores, where they were introduced by the Portuguese; but very good ones are brought from Portugal, Spain, and Malta: some also grow in the south of France and Italy, but they are inferior.

The orange-tree may be mentioned as an instance of extraordinary fecundity: a single tree at St. Michael's has been known to bear in a season 20,000 oranges fit for packing, exclusive of those damaged and wasted, amounting to at least one third more. The delightful perfume of an orange-grove is such as to scent the air for miles, and the tree gives a succession of flowers during the whole summer.

Magnificent conservatories have been erected for them in countries where they do not bear the cold of winter. The first orange-trees were brought to England by Sir Walter Raleigh. At Hampton Court there are some said to be 300 years old; these, and also some at Windsor, are kept in green-houses during the winter, and are wheeled into the open air about the middle of June, when the perfume of their flowers is delicious. In point of age, these are far surpassed by those at Cordova, in Spain, the seat of ancient Moorish grandeur: some trees there are said to be six or seven hundred years old. In Devonshire and in other parts of England they have produced fine fruit when trained against walls and sheltered with mats. At Mr. Pugh's villa, at Rouen, there is a collection of a hundred orange-trees in boxes above seventeen feet high, and several centuries old; in winter they are kept under cover. In 1823 these produced 1400 lbs. of blossoms, which sell, on an average of years, at 2*s*. 4*d*. per pound, for the purpose of making orange-flower water.

2619. *The agreeable sub-acid of the orange* renders it one of the most agreeable, cooling, and wholesome of fruits; and the essential oil in the rind is serviceable to the cook in giving flavour to many dishes.

2620. *The varieties of the orange are numerous;* but the most important, as enumerated by Professor Burnett, are, 1, the common sweet orange; 2, the China; 3, the Majorca; 4, the Nice; 5, the Genoa; 6, the thick-rinded Portugal; 7, the tea-fruited; 8, the double-flowered; 9, the ribbed; 10, Malta, or blood-juiced; 11, the St. Michael's; and, 12, the Oporto, or pipless pot oranges.

2621. *It is observed in the Library of Entertaining Knowledge:* "The extraordinary consumption of a production which is brought here from very distant places is a natural consequence of certain qualities which fit the orange, in a remarkable degree, for being the universal fruit of commerce. If we would have foreign figs and grapes, they must be dried, for the undried grapes, which we bring even from the short distance of Portugal, are flat and vapid; the tamarind is a liquid preserve; the guava must be made into a jelly; the mango destined for us requires to be pulled before it is ripe, and is pickled; the date must be dried; and the cocoanut becomes, when here, consolidated and indigestible. With regard to the orange, man may have it fresh in every region of the world, and at almost every season of the year. The aromatic oil and the rind preserve it from the effects both of heat and cold; and the acridity of the former renders it proof against the attacks of insects. It is true that oranges rot, like other fruits; but that does not happen for a long time, if the rind is uninjured and they are kept from moisture, and so ventilated as not to ferment."

SUBSECT. 2.—*Seville Orange* (*Citrus Vulgaris*).

2622. This variety, called also the *bitter orange*, is of the same species as the sweet orange, and grows in great abundance on the banks of the Guadalquivir in Andalusia, from which they are chiefly obtained. In that part of Spain there are very extensive orchards of these oranges, which form the chief wealth of the monasteries. The pulp of the bitter orange is not eaten raw; in the yellow rind, separated from the white, spongy substance immediately below it, there is contained an essential oil, which is an agreeable warm aromatic, much superior for many purposes to that of the common orange. The best marmalade and the richest wine are made from this orange, and it is from the flowers of this that the best orange-flower water is distilled. They are also preserved whole as a sweetmeat.

SUBSECT. 3.—*Lemon* (*Citrus Limonum*).

2623. The lemon or citron tribe are natives of Asia, and appear to have been well known to the Romans: they are mentioned by Virgil and Pliny, but only as foreign fruit, and as antidotes against poison. It does not appear that they cultivated them. The citron is found wild in that part of India which is beyond the Ganges; also in Assyria and Persia, and was brought into Europe by the Arabians. It is now abundant in the south of France, Italy, Spain, and the West Indies.

The lemon is hardier than the orange. In some parts of Devonshire lemon-trees are trained to the walls, and require no more than a covering of straw or mats during the winter. Earl Paulet presented some of these lemons to George III. upward of fifty years ago, which grew in the garden of his sister, Lady Bridget Buttord. They were first cultivated in this country in the reign of James I., and are now not uncommon in our green-houses.

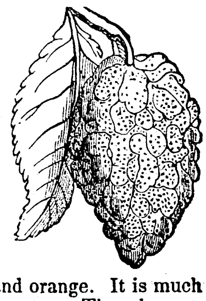
2624. The fruit in common use, however, is imported from Spain, Portugal, and the Azores, packed in paper, in the same manner as oranges. The Spanish are the most esteemed; those of St. Helena are extremely fine, growing larger and milder than the others. This fruit is not an article of mere luxury, but is almost an essential for culinary and many other purposes. The juice consists chiefly of the *citric acid*, which, besides its agreeable flavour, is particularly cooling and grateful. But the discovery of its antiscorbutic influence gives it a still higher value.

2625. *The scurvy, formerly so fatal in ships* making long voyages, is now *almost wholly unknown* in them: a result that is, in a great measure, to be attributed to the *regular allowance of lemon juice* served out to the men. The juice may be preserved in bottles for a considerable time by covering it with a thin stratum of oil; thus secured, great quantities of it are exported from Italy and Turkey to various parts of the world; it is also frequently administered as a medicine, and is extensively employed in the manufacture of punch. The citric acid is also prepared in a pure state, and crystallized, by which means it can be preserved in any climate, and for any length of time; but it is found that the crystallized acid is inferior to the recent juice. *Shrub* is made of lemon juice, sugar, and rum.

2626. *The outward rind or peel of the lemon contains* a highly odoriferous essential oil, and on that account it is a valuable and agreeable stomachic, and is used for flavouring a variety of dishes; it is warm, aromatic, and slightly bitter: it is also made into an excellent sweetmeat when cleared of the pulp and preserved by sugar, well known by the name of *candied lemon peel*. A liqueur is made by the inhabitants of Barbadoes from lemon peel, in a manner peculiar to themselves, called *Eau de Barbade*.

Subsect. 4.—*Citron* (*Citrus Medica*, Linn.).

Fig. 513.

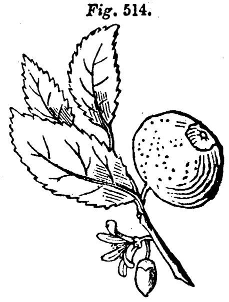


2627. This fruit (*fig.* 513) belongs to the same species as the lemon, being considered only as a variety, the distinction between them not being very great. It is larger and less succulent, but more acid; with a little artificial heat the citron comes to as great perfection in England as in Spain and Italy. The fruit is oblong, and about five or six inches in length. The tree is thorny. The juice forms an excellent lemonade with sugar and water. Its uses in punch, negus, and in medicine, are well known. The rind is very thick, and, when candied with sugar, forms an excellent sweetmeat. There are several varieties cultivated in England, one of which is termed the *forbidden fruit.*

Subsect. 5.—*Shaddock* (*Citrus Decumana*).

2628. This is also a variety of the same species as the lemon and orange. It is much larger than these, the fruit being from three to six inches in diameter. Though a native of China, it is cultivated largely in the West Indies, where it was first carried by Captain Shaddock. In its native country it is a sweet fruit, with little acidity; but in the West Indies, through neglect in its cultivation, it has degenerated into a sour fruit. It is handsome, and contains abundance of juice, which, diluted, is used as a beverage, and in making punch. Though less agreeable in its flavour than the orange, it keeps fresh and good longer at sea: hence it is valuable.

Fig. 514.



Subsect. 6.—*Lime* (*Citrus Acida*, Rox.).

2629. This (*fig.* 514) is also a variety of the lemon, but much smaller, being only about an inch or an inch and a half in diameter. It is not much cultivated in Europe, but, being more acid and cooling than the lemon, it is a great favourite in the West Indies, where lime punch is more esteemed than any other. The greatest part of our citric acid is prepared from its juice. There are several varieties.

Sect. V.—pulpy fruits.

2630. These have their seeds lying among the pulp, and are not enclosed in a nut or membrane like the grape.

Subsect. 1.—*Pineapple* (*Bromelia Ananas*, Linn.).

2631. It is the gardener's boast that this delicious fruit is produced in every part of Britain, by the employment of artificial heat, in greater perfection, both as to size and flavour, than in the West Indies, where the climate is natural to them. It grows wild in vast abundance in many parts of Africa and South America, and is cultivated in the hotter islands of the West Indies, where it requires but little attention to procure this elegant fruit in perfection and plenty. In Jamaica, pineapples have become so prolific that they are often used to flavour rum, and a wine is made from the fermented juice of the sweeter sorts nearly equal to malmsey.

2632. It has not been known in Europe above two hundred years, and has not been cultivated in England much above a century. It is stated that the first pine-apples raised in Europe were by M. la Cour, of Leyden, about the middle of the seventeenth century, and it is said to have been first cultivated in England by Sir Matthew Decker, of Richmond. In Kensington Palace there is a picture in which Charles II. is represented as receiving a pineapple from his gardener, Rose, who is presenting it on his knees.

2633. *At present, pineapples may be procured* any day of the year in London with more certainty than in their native countries, and of late their price has been very much reduced. It derives its name, probably, from the resemblance which the form of the fruit bears to that of the cone of the pine. This fruit is formed of many clustered tubercles, supporting crimson flowers: on the summit stands a crown of clustered leaves. While the fruit is growing, spines shoot out on all sides; but as it approaches maturity, these become dry and soft. It should be cut a little before it is quite ripe, and kept a few days. The largest pineapple ever grown in this kingdom was cut lately from the hot-house of John Edwards, Esq., of Rheda, Glamorganshire, and was presented to the king at Windsor. It weighed 14 lbs. 12 oz. avoirdupois, was 12½ inches high, exclusive of the crown, and 26 inches in circumference. It is the first of dessert fruits, and is, likewise, preserved in sugar, and made into marmalade. The malic and citric acids, which give to the juices, when fully ripe, their exquisite flavour, are abundant before maturity; the unripe juice is said even to have caustic properties, and at all times is so powerful as to corrode the knives with which the fruit is cut. In England, after the crown has been twisted off, the fruit is cut in horizontal slices; but in the West Indies it is cut obliquely, in the direction of the pips.

Subsect. 2.—*Grape* (*Vitis Vinifera*, Linn.).

2634. Next to the pineapple, grapes, when in perfection, have always been considered the most delicious fruit for the dessert.

2635. *The early history of the vine* is involved in the same obscurity as that of most of our vegetable productions. Its antiquity is unknown; but from the Scriptures we learn that its cultivation was of very early date. Bacchus was imagined to have taught its use in making wine, and was, in consequence, elevated to the rank of a god. Humboldt says that the vine now cultivated in Europe grows wild on the banks of the Caspian Sea, and in Armenia, which countries and Persia are probably its native place. From Asia it passed into Greece and Egypt, and thence into Italy and the rest of Europe. The Romans planted it on the banks of the Rhine; and France, now so remarkable for the excellence of its grapes, possessed none in the time of Strabo. It appears to have been brought into England towards the close of the Roman power, and in the time of the Anglo-Saxons it was cultivated in several parts of England; afterward, while the monasteries existed, few of them were without their vineyard.

It is a curious and interesting fact, which we shall enlarge upon in our account of wines, that in ancient times large quantities of wine were annually made in Britain. This has been supposed by some to indicate a change in our climate, an opinion, however, which is not sufficiently supported.

2636. *The grape vine has a limited range of latitude*, extending from the twenty-first to the fiftieth degree of N. latitude. Some varieties of it are found wild in America, particularly on the banks of the Ohio, where the French settlers have made tolerable wine from it. It is also cultivated in the same situation in the southern hemisphere, in South America, the Cape of Good Hope, and Australia.

2637. *Abundance of grapes ripen against walls in England* at present, but the best sorts are raised in vineries and hot-houses; the former are so common that there is scarcely a kitchen-garden worth notice without one; and, with the improvements of modern gardening, our hot-house grapes are not inferior in flavour to any produced in any part of the world.

2638. *The luxuriance and size of the vine in warm climates* is so great that it would scarcely be credited here, were it not well authenticated. Strabo relates that some bunches of grapes in Italy were a yard across. Bunches have been grown in Syria forty pounds in weight, but these are of a distinct species of grape. In England the bunches are usually from two to seven pounds, but they have been known to reach nineteen pounds.

The great vine at Hampton Court, planted in 1769, of the variety called black Hamburgh, occupies a space of 116 square yards, and has a stem thirteen inches in circumference; one branch is 114 feet long; it is a most productive bearer, having seldom fewer than 2000 bunches upon it every season, each weighing a pound on an average, or in all nearly a ton. Its parent, still existing in Valentine House in Essex, planted in 1758, is still larger, and nearly as productive.

2639. *The varieties of grapes are extremely numerous:* vine-growers enumerate in their catalogues nearly three hundred, of which between fifty and sixty are cultivated in Britain. These are classed according to the form and colour of the fruit, and are thus stated by Professor Burnett, in his "Outlines of Botany:" 1, the round black, or purple grapes; the grapes from which port wine is made belong to these; 2, the long black ones, to which belong the Hamburgh grapes; 3, the round white, or green grapes; 4, the long white and green ones; to the last two belong those brought from Portugal and Spain, packed in earthern jars; 5, the grapes of any other colours, such as red, roseate, blue, grayish, or variegated in stripes.

2640. *Of the round black grapes*, the most esteemed are the Damascus, the black Lisbon, the Muscat or purple Constantia, and the black Morocco. The claret grape is remarkable for its juicy pulp, being of a deep purple or blood colour, while in the others the dark tint is confined to the skin. The Ascalon, or black Corinth, when dried, constitutes the *currants* of commerce.

2641. *Of the long black grapes*, the best are Muscadel, the Burgundy, the purple Hamburgh, the black raisin, and the black Palestine.

2642. *Of the round white grapes*, the amber Muscadine, the malmsey Muscadine, the white Muscadine, the Pearl-drop, and the white Constantia are all excellent. The white Corinth or Ascalon is often without pips, and, when dried, is known as *Sultana* raisins.

2643. *Of the long white grapes*, the white Sokars, the white Muscat, the Morillon, or genuine Tokay, the white raisin, and others might be mentioned. The Verdelho, from which Madeira is made, is an excellent grape, but the stones should be rejected, as they are said to be deleterious when eaten.

2644. *Of the fancy grapes*, the red Muscat, the blue Tokay, the striped Aleppo, and the variegated Chasselas, are all worthy of cultivation.

2645. *Switzer informs us* that it is to Lord Capel and Sir William Temple we owe that collection of good grapes now so plentiful in England. The latter brought over the Chasselas and Frontignan, Amboyna, Burgundy, black Muscat, and grizzly Frontignan, and distributed them among the nurserymen, nobility, and gentry.

2646. *Grapes for the dessert* should be of a fine flavour, thin-skinned, sweet, and juicy. There is a superior richness in the black, blue, and red Frontignans, and there is a peculiar delicacy in the flesh of the white sweet water, which is also remarkably thin-skinned, with large berries. Grapes of the green and black sorts are imported from Portugal, and likewise from Malaga, and other parts of Spain, packed in large earthen jars having the interstices filled up with chaff, and the lids cemented down. They arrive here in little less than a week by the steam-packets. This method of preserving grapes was known to the Romans, and is described by Columella. Grapes are also brought from Hamburgh and Frankenthal, and sold at one shilling, and even eight pence per pound: arriving in less than twenty-four hours from Holland, they have all the plumpness and bloom of fresh-gathered fruit.

2647. *Used as food*, grapes are extremely nutritive in general, and very wholesome if quite ripe. They are better eaten with bread, as is the case in France, where they form a frequent breakfast for the working classes. Of the juice of unripe grapes, a pleasant cooling summer beverage is made; but the fruit should not be eaten in that state. The chemical composition of grape juice will be stated when treating of the mode of making grape wine.

2648. *Raisins* are grapes that have been allowed to shrivel and dry partly on the tree; they are then cut off and dried in the sun; hence they are sometimes called *sun raisins*, to distinguish them from others dried in ovens. They are also called *jar raisins*, because they come to us in jars. By drying they lose about two thirds of their weight, and become covered with a saccharine exudation. Some raisins come from Spain, Calabria, Smyrna, &c. The Malaga are the largest and most highly prized for the table, known here generally as *Muscatel*, and sell for double the price of any other. They are the produce of the provinces of Valentia and Grenada. On the hills round Malaga there are upward of 7000 vineyards. The first gathering of grapes for some raisins commences in June; from those gathered in September, *Xeres Secco*, or *sherry*, is made, the sack of Shakspeare; and a third, in October and November, produces the wine known on the Continent as *Malaga*, and in England as *mountain*. *Common raisins* are made from various kinds of grapes, better or worse; they have a slight degree of acidity, which renders them less agreeable than the best.

2649. *Dried currants*, so much used in Christmas pies and puddings, are a kind of little raisins, or dried grapes, that grow in, and are brought from, the Ionian Islands. The chief place from which they were formerly imported was the Morea, or the Isthmus of Corinth, whence the name, *corinths*, converted into *currants*.

2650. The island of Zante is the chief place from which currants are now brought; some are from Cephalonia and Ithaca. When they are collected in August from the vines, which grow quite low, they are spread out and dried in the sun, and then packed in casks quite close till they are wanted. They get thus so fixed together that they require to be dug out with an iron instrument. See, farther, on the subject of grapes, in Book VIII., Chap. IV., "On Wines."

Subsect. 3.—*Melon* (*Cucumis Melo*, Linn.).

2651. The flesh of this fruit is very delicious, being succulent, cool, and high-flavoured. With us it is used only at the dessert, and is generally eaten with sugar, ginger, or pepper; but in France it is likewise served up at dinner as a sauce for boiled meats. It grows wild in Tartary, and has been lately found in abundance on the sandy plains of Icypoor. It was brought originally from Asia by the Romans, and is said to have been common in England in the time of Edward III., though it is supposed that it was lost again, as well as the cucumber, during the wars of York and Lancaster.

The best kind, called the *Cantaloupe*, from the name of a place near Rome where it was first cultivated in Europe, is a native of Armenia, where it grows so plentifully that a horse load may be bought for a crown.

Melons require a high temperature to raise them in perfection; and though no country has a greater variety of them than England, yet they have a high price in our markets. In France they are grown in such abundance that whole villages are occupied exclusively with their cultivation; and, in consequence of the practice which the people have, their culture is well understood. While in France and England melons are grown as articles of luxury, in some parts of the East they are used as necessaries of life. Niebuhr informs us that in Africa melons are planted in the fields, and that they are used by all ranks of Arabians as common food.

2652. *But although the melon is a very delicious fruit, it is not one of the most wholesome*; and the coldness of its nature demands that it should be accompanied by warm and stimulating condiments. Large melons are too often preferred on account of their showy appearance; but the small ones, when ripe, are often the most highly flavoured. There are many varieties of this fruit of several degrees of excellence. When a melon is perfectly fine, it is full without any vacuity; this is known by knocking upon it; and when cut, the flesh should be dry, no water running out, only a little dew, which should be of a fine reddish colour.

2653. *The watermelon* requires a warm climate to bring it to perfection in the open air. Its sweet and succulent flesh, and gratefully cool juice, render it particularly agreeable in those countries where it grows abundantly. The juice is sucked out by a hole made in the rind. In Upper Egypt, whole districts on the banks of rivers are planted with watermelons; they grow in sand. The Egyptians eat them in such abundance that they would seem to be almost their only meat and drink, and they form their most common medicine in cases of ardent fever; but Hasselquist recommends caution in their use, "as they chilled his stomach like ice." The fruit often grows to a large size in this country; but in Senegal one has been known to weigh sixty pounds. In some parts of India, where rain does not fall for fifteen months, watermelons sometimes weigh from fifteen to seventy pounds. They were introduced into England with the common melon, but are seldom cultivated, as the juice, though useful in a warm climate, is insipid. One kind of watermelon is pickled like gherkins, and is much used by the French cooks in their fricassees; it is also sometimes baked in sweet wine.

SUBSECT. 4.—*Cucumber* (*Cucumis Sativus*, Linn.).

2654. *This fruit is allied to the melon*, though far inferior in point of flavour. It appears to have been cultivated at a very early period, for it is mentioned in the Mosaic history as one of the fruits which the Israelites enjoyed in Egypt, and of which they regretted the loss. We are informed by travellers that it, together with other fruits of this class, still forms a great part of the food of the people in Egypt. Bishop Heber saw them raised in India beyond the Ganges, and Burckhardt observed them in Palestine. Pliny mentions them as growing in great quantities in Africa. It was a very great favourite among the Romans, who raised them by artificial heat, and they were introduced into England together with the melon.

2655. *Cucumbers are chiefly used as salad with meat or fish*, and *young* ones are pickled under the name of *gherkins*. They are cold, and more difficult of digestion than most vegetables when eaten raw; and they are generally dressed with pepper, vinegar, and oil, chiefly with a view to correct their cold qualities. Cucumbers are now much less used in their natural state than formerly among wealthy families; but they are in request for stews and made dishes, and when preserved they are esteemed one of the most agreeable sweetmeats. They are excellent, and more wholesome when stewed with gravy. The expressed juice of the cucumber is employed as a cosmetic, giving a pleasant suppleness to the skin, and it enters into the composition of several French pomades.

SUBSECT. 5.—*Fig* (*Ficus Carica*).

2656. *The fig-tree is a native of Asia*, and was known to the Israelites, as we learn from the Scriptures. The fruit appears to have formed a principal article of food among the inhabitants of ancient Syria and Greece, and was so much esteemed for its nutritive qualities, that it was considered as an emblem of fruitfulness. Like the cerealia, it enjoys a considerable range of latitude.

Dried figs and barley-bread are a general food among the lower classes of Greece in the present day. In the northern parts of France there are many fig gardens; but it is not generally cultivated in England, except on walls, or in the hot-house, the climate being scarcely warm enough to admit of its flourishing as a standard in the open air; nevertheless, it will ripen its fruit in some open situations in the south part of England. There is an orchard of fig-trees at Tarring, near Worthing, where the fruit ripens nearly as well as in Spain, and the trees are exceedingly productive. There are also some fig-trees above thirty feet high in the gardens at Arundel Castle. Figs grow, likewise, in some other places, and there is no doubt that they could be easily raised for fruit on the coast of Sussex, if sufficient attention were paid to that object. It is generally supposed that the fig was not planted in England before the reign of Henry VIII., when the arts began to be encouraged, and noblemen's houses first put on the air of Italian magnificence. There are at present some fig-trees in the Episcopal Gardens at Lambeth, said to have been planted by Cardinal Pole; and at Oxford, in the Botanic Garden of the Regius Professor of Hebrew, there is a fig-tree which was brought from the East, and planted by Dr. Pococke in 1648.

2657. *The fig contains* a large portion of sugar, without acidity or oiliness, and is of easier digestion than any other of the sweet fruits. They are considered to be laxative.

2658. *The best dried kinds* come from Turkey, Italy, Provence, and Spain. Smyrna is a great mart; but the figs of the Grecian Archipelago are inferior to those of Europe. Figs are prepared by dipping the ripe fruit in a scalding hot lye made of the ashes of the fig-tree, and then dried in the sun, or in ovens, and packed very close in chests. In the Canaries, Portugal, and the Grecian islands they make a kind of brandy from them.

In medicine, figs are employed as emollient cataplasms and pectoral decoctions

SUBSECT. 6.—*Tamarind* (*Tamarindus Indica*).

2659. The tamarind is the fruit, or, rather, pod of a tree which is a native of the East and West Indies, and thrives also in Egypt, Palestine, and Arabia. In the countries where it is produced it forms occasionally an article of food, in the form of confectionery, and is esteemed on account of its pleasant acid and cooling qualities, so useful in a warm climate. The pod consists of two parts; the outer is fleshy, and the inner thin as the finest parchment: between these two there is a space of about a quarter of an inch, which is filled up with a soft, pulpy substance of a tart but agreeable taste; this, and the seeds which are enclosed in the inner pod, are fastened together by many slender fibres from the woody stalk which runs through the pod. The tree is common in Jamaica, is extremely beautiful, and grows to a great size, with large, spreading branches, and a thick and luxuriant foliage. The pods are gathered when ripe, freed from the shelly fragments, and placed in layers in a cask; boiling sirup is then poured over them till the cask is filled; the sirup pervades every part quite to the bottom, and when cool the heads of the casks are fixed down for sale. The more elegant method, however, is to clarify the juice of the fruit with the white of eggs, and form it with sugar into a clear, transparent sirup; this or the fruit supplies an agreeable and cooling beverage. The East India tamarinds are generally preserved by putting alternate layers of tamarinds and powdered sugar into a stone jar, by which means the fruit retains more of its natural taste and appearance. They are also sent from the East Indies in their natural state without sugar; but except these are kept in very close jars, they are apt to get musty.

2660. *According to Vauquelin, tamarinds contain* in the pulp, independent of the sugar used to preserve it, super-tartrate of potassa, gum, jelly, citric acid, tartaric acid, malic acid, and a feculent matter. The acid taste depends chiefly upon the citric acid, the quantity of that being the greatest.

Sect. VI.—nuts.

2661. *These are seeds or fruits rather dry*, and not fleshy or pulpy, enclosed in a hard woody shell or husk. Nuts of various kinds are spoken of as much employed for food in ancient times, and they still furnish in some countries a considerable source of aliment.

2662. *The edible part, or kernel, usually contains a good deal of oil*, and although they are nutritive, they are less digestible than most other vegetable substances. The principal fruits of this class used as food in England are the walnut, chestnut, and filbert, grown in England, to which we may add the acorn, the exotics, cocoanut, cashew nut, and pistachio nut.

Subsect. 1.—*Walnut* (*Juglans Regia*, Linn.).

2663. The walnut is a native of Persia, the Caucasus, and China, but was introduced to this kingdom from France.

2664. *The ripe kernel is brought to the dessert* on account of its agreeable flavour, and the fruit is also much used in the green state, before the stone hardens, as a pickle. In Spain grated walnuts are employed in tarts and other dishes. The walnut abounds in oil, which is expressed, and which, being of a highly drying nature, and very limpid, is much employed for delicate painting. This, on the Continent, is sometimes used as a substitute for olive oil in cooking, but is very apt to turn rancid. It is also manufactured into a kind of soap. The marc, or refuse matter after the oil is extracted, proves very nutritious for poultry or other domestic animals; in Switzerland this is eaten by poor people, under the name of *pain amer*.

2665. The sap of the walnut-tree is very saccharine, and sugar may be made from it by evaporation; it may also be fermented into a kind of wine. The leaves and green husks afford an extract, by maceration in warm water, that acts as a very permanent brown dye for staining hair, wool, and wood, and is said to be employed by the gipsies to give a dark colour to children whom they have stolen.

Subsect. 2.—*Chestnut* (*Fagus Castanea*, Linn.).

2666. The chestnut was known to the Romans, who called it Castanea, from a city of that name in Thessaly, whence they first procured it; and it was grown abundantly by the ancients, and much used as food. It is so common in Italy and France that it is often considered to be a native of these countries. The chestnut lives to a very great age, and forms some of the oldest trees in the world; as the celebrated one mentioned by Brydone on Mount Ætna, under which a hundred horsemen are said once to have taken shelter; that at Fortworth in Gloucestershire, and one at Marsham, calculated to be 1100 years old. This tree was probably introduced into England by the Romans. It grows commonly in the warmer parts of Britain; but the fruit seldom comes to maturity in Scotland.

2667. In the southern parts of the Continent, chestnuts form a very large portion of the food of the labouring classes, who, besides eating them both raw and roasted, make puddings of them, and polenta for pastry. Boiled chestnuts and milk form a common breakfast among the peasantry in the south of France; and in Corsica, as well as several districts of Spain, they are cooked in various ways. Mr. Phillips says (*Pomarium Brit.*, p. 95), "Chestnuts stewed with cream make a much admired dish, and many families prefer them to all other stuffings for turkeys: they make an excellent soup, and I have no doubt but that chestnuts might be advantageously used in cooking, so as to make many agreeable and wholesome dishes. I have had them stewed and brought to table with salt fish, when they have been much admired; but it is exceedingly difficult to introduce any article as food that has not been established by long custom; and it is not more strange than true that the difficulty increases if the object be economy."

2668. The chestnuts that grow commonly in this country are inferior in size and perfection to those which are imported from Spain, Portugal, and Italy: these are frequently kiln-dried to prevent germination in the passage. In Britain, little use is made of the chestnut except at the dessert, for which it is roasted, when it becomes farinaceous or mealy, like a sweet potato.

2669. It is, indeed, the most farinaceous and the least oily of all the nuts, and therefore it is the most easy of digestion; but raw chestnuts are not digestible by every one.

2670. *The tree called the horse-chestnut*, from the resemblance of its fruit to that of the chestnut, is very different. Its fruits are astringent and bitter, and unfit for human food; nevertheless, they contain so much farinaceous matter, that they are very nutritious to some animals, and horses and deer devour them greedily. They are likewise detergent, and have been used as a substitute for soap. A patent was taken out some years ago for preparing starch from them, by which much esculent grain might be saved.

Subsect. 3.—*Hazelnuts and Filberts* (*Corylus Avellana*, Linn.).

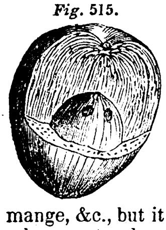
2671. *The common hazel is the wild, and the filbert the cultivated state of the same tree.* The hazel is found wild, not only in forests and hedges, in dingles and ravines, but occurs in extensive tracts in the more northern and mountainous parts of the country. It was formerly one of the most abundant of those trees which are indigenous in this island. It is seldom cultivated as a fruit tree, though, perhaps, its nuts are superior in flavour to the others. The *Spanish nuts* imported are a superior kind, but they are somewhat oily, and rather indigestible. *Filberts*, both the red and the white, and the cob-nut are supposed to be merely varieties of the common hazel, which have been produced, partly by the superiority of soil and climate, and partly by culture. They were originally brought out of Greece to Italy, from whence they have found their way to Holland, and from that to England. It is supposed that, within a few miles of Maidstone, in Kent, there are more filberts growing than in all England besides; and it is from that place that the London market is supplied. The filbert is longer than the common nut, though of the same thickness, and has a larger kernel. The cob-nut is a still larger variety, and is roundish. Filberts are more esteemed at the dessert than common nuts, and are generally eaten with salt. They are very free from oil, and disagree with few persons.

Subsect. 4.—*Cocoanut.*

2672. *This magnificent nut* is the produce of one of the palms (*Cocos nucifera*) which grows wild abundantly in the eastern parts of Asia and the islands of the Indian seas, from which it has been introduced into every part of the tropical regions, the property which the fruit has of not being destroyed by sea-water, favouring its transportation. The tree, like the rest of the palms, is tall and straight, being from thirty to sixty feet in height, and sometimes more, having the leaves only at the top, and the nuts hanging in bunches of about a dozen each, under the leaves: one tree, in a good soil, has sometimes a hundred cocoanuts annually. Some trees will bear blossoms every four or five weeks; hence there are generally fresh flowers and ripe nuts on the tree at the same time. The tree will continue to flourish for a century.

2673. The fruit is covered externally by a thin, tough rind, of a brownish-red colour.

Fig. 515.



Immediately within this is a quantity of tough fibres (*fig.* 515); and in the midst is enclosed the nut itself, which consists of a very hard shell, containing a kernel of a white substance, being itself hollow. The kernel, in its fresh state, is very nutritive, containing a good deal of fixed oil: it is eaten raw, or made into cakes or fritters when rasped; but, when it arrives in England, it is generally dry and indigestible. While the nut is green, the whole of the shell is filled with a juice called the milk, which is agreeably sweet and refreshing. When this can be procured, in its native country, it forms a delicious beverage; it is used as milk with coffee, and is employed for custards, blanc-mange, &c., but it is seldom found in any quantity in the cocoanuts brought to England: a large nut, when fresh, will give half a pint of milk. When it is very young, the pulp is so soft that it may be eaten with a spoon, and, with a little Madeira wine and lime juice, is excellent. When about a quarter ripe, the shell is thin, and so transparent that it is used to hold a light by way of a lantern: there are three holes in it, which give it somewhat the appearance of a monkey's head; from one of these the germe, or young plant, rises when the nut is planted in the ground. The oil obtained by pressure from the kernel is used for burning in lamps.

2674. *Perhaps no tree furnishes so many useful products as the cocoa*, and, where it exists in abundance, it seems to supply almost all the necessaries of life. The woody shell of the trunk, when of considerable age, is tough and durable, and is employed in building huts; it is sometimes so hard as even to be capable of receiving a very fine polish. The terminal leaf buds at the top of the tree are very tender and delicate, and, when boiled, resemble cabbage: they are pickled with vinegar; but they can be had only at the expense of the tree, which dies if they are cut off. The bases of the leaf-stalks afford a reticulated substance, like gauze, that is used by the Indians for coverings for cradles and for strainers. The leaves themselves are used for thatching houses, and ceilings are formed of them. Various articles are also manufactured from them, as baskets and wicker-work; also masks to protect the face from the sun: when young they are transparent, have a fine texture like satin, and are used for making lanterns; they are also employed for writing upon by scratching with a pointed iron instrument. Of the small leaves baskets for catching fish are made; also combs and brooms. They serve also for fuel, and for torches in travelling, and to keep off wild beasts; their ashes, which contain much alkali, are used for washing or making soap. The central rib of the leaf is employed for oars; and the end of it, well bruised, answers as a broom or a brush for whitewashing. The fibrous coverings of the blossoms are made into aprons or petticoats for women. The fibres in the nut afford a material of which ropes and strong cables are twisted, which endure in salt water much better than those of hemp, and are even employed in manufacturing course sail-cloth: they are likewise used for stuffing mattresses, cushions, &c. The marc, or refuse of the nut after the oil is expressed, serves as food for cattle; and the roots of the tree are sometimes chewed by the Indians instead of areca or betel nut. Of the shell of the nut a great variety of drinking-cups, ladles, spoons, and vessels of various kinds are made. From the sap of the tree, called toddy, arrack, a fermented liquor, is produced, superior to that from rice. When fresh toddy is boiled over a slow fire, it thickens into a sweet luscious substance, named *honey;* and, if this is farther boiled, it forms a coarse brown sugar, called *jaggery,* which is often dried into round cakes for keeping. In short, there is no part of the tree but is employed for some useful purpose, and it is certainly one of the most valuable gifts bestowed by Providence upon the inhabitants of tropical climates; and yet, with respect to fruit, the cocoanut tree is one of the least productive of the palm tribe. Another species of this class, the *Seje* palm, bears 8000 fruits at once; a single spathe of the date palm contains 12,000 flowers, each of which should afford one fruit; and in a third species, the *Alfonsia Amygdalina,* there is the enormous number of 207,000 flowers on each spathe.

2675. *The cacaonut,* pronounced, improperly, *cocoa,* from which our chocolate is made, is a very different fruit from that just described; and as it is not eaten as a fruit, we shall reserve our account of it to the description of "Cocoa used as a Beverage," Book VIII., Chap. XII.

SUBSECT. 5.—*Date* (*Phœnix Dactilifera,* Linn.).

2676. *This is the fruit of one of the palm tribe,* and forms a principal part of the food among the Arabs and inhabitants on the margin of the great sandy deserts in the north of Africa, where there is scarcely any other esculent vegetable. There this majestic monarch of the thirsty land, affording the only shade and food to be met with, is hailed by the traveller with greater pleasure than, perhaps, any tree in another situation. It shoots up a single straight stem to the height of fifty or sixty feet, and then throws out a magnificent crown of leaves, graceful and pinnated.

2677. The fruit, before it is ripe, is somewhat astringent, but when thoroughly mature it is excellent, being rich in sugar, gum, and other vegetable matter, with little acid; it is extremely agreeable and sweet, and affords wholesome nutriment. If required to be kept or transported, it must be dried in the sun. The Arabs reduce dates, when dried, to a kind of meal, which they preserve for food when they undertake long journeys across the deserts, and they will subsist for a considerable time upon date-bread.

2678. In Egypt an agreeable conserve is made of fresh ripe dates. They form a kind of solid paste or cake of them, by pressing them into baskets while soft, and in this state they are brought to market, and cut out in lumps, which are sold by weight for the daily food of the inhabitants. Mixed with water, they also compose a refreshing drink. The wood and leaves of the date-tree serve for many of the same uses to which the cocoanut palm is applied, above mentioned.

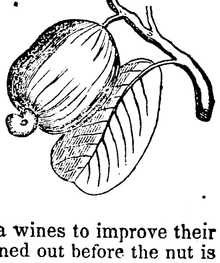
2679. *Dr. Clarke observes that a single date palm* will bear upward of a hundred weight, and sometimes between two and three hundred weight of dates in a season: they come into bearing at about six to ten years of age, and are fruitful for upward of two hundred years. The young shoots are good to eat, and resemble asparagus. The stem of the date-tree likewise affords an inferior kind of sago, and from its juice a fermented liquor is made.

2680. *Dates are imported into Britain in a dried state* from Barbary and Egypt, and, when in good condition, they are much esteemed. An inferior kind has lately become common, which are dried hard, and have little or no flavour. They should be chosen large, softish, not much wrinkled, of a reddish yellow colour on the outside, with a whitish membrane between the flesh and the stone.

SUBSECT. 6.—*Cashew Nut* (*Anacardium Occidentale,* Linn.).

2681. This is a tropical production. The nut (*fig.* 516), which a good deal resembles the walnut, grows at the end of the fleshy, pea-shaped receptacle called the apple. It has an agreeable sub-acid taste, and may be fermented into a kind of wine. The juice is also much used in the West Indies for making punch and other beverages.

Fig. 516.



2682. The eatable kernel is contained within two shells, and between these shells there is a thick rust-coloured liquor, extremely inflammable, and so caustic that it will blister the skin: this is used as an indelible marking ink for linen. The kernel is of a very fine flavour, preferable to the walnut, and employed in puddings and many other compositions of the cook, abounding in a delicious milky juice when fresh, and may be eaten raw, roasted, or pickled. Some also grind it with cacao in making chocolate, the flavour of which it is said to improve.

2683. The broken nuts are used for steeping in old Madeira wines to improve their flavour. The acrid inflammable oil of the shell should be burned out before the nut is eaten; for, if incautiously cracked by the hands or teeth, the caustic oil will blister the lips and excoriate the skin where it touches. It is said that the milky juice of the tree itself, obtained by tapping or incision, forms a black marking ink for linen that cannot be washed out. The nuts are eaten abundantly by the negroes in Brazil.

SUBSECT. 7.—*Pistachio Nuts* (*Pistachia Vera*).

2684. These nuts are brought to us from Sicily and Syria, where they grow upon a kind of turpentine-tree. They are oblong and pointed, about the size and shape of a filbert, including a kernel of a pale greenish-colour. Their taste is very agreeable, much resembling that of sweet almonds; but they are sweeter, have more flavour, and are more oily; hence they are liable to become rancid. On the Continent, in places where they are plentiful, they enter into the composition of ragouts and various dishes. A variety (*P. Atlantica*) is slightly acid, and is made, with dates, into cakes by the Arabs.

SUBSECT. 8.—*Brazil Nut.*

2685. These are also called *chestnuts of Brazil*, and are brought to us from Para. They are much esteemed, having a kernel resembling that of the almond, but larger, containing a great deal of oil, and tasting more like the hazelnut. The kernel, of a wedge-like form, is found within a very hard shell, as large as a child's head, which grows in clusters of fifteen or twenty. The tree which produces them is a Juvia, rising to the height of 100 or 120 feet, and abounding on the banks of the Oronoco.

SUBSECT. 9.—*Acorn.*

2686. The acorn, which is the well-known fruit or nut of the *oak-tree* (*Quercus*, Linn.), formed part of the food of man in the early ages, before the use of corn was known, and frequent allusion is made to this circumstance by the classic writers. They are seldom used at present, except for the fattening of hogs, deer, and poultry.

It is not certain that the acorn was ever employed as the common food of the inhabitants of this island, although they might have been among the ancient Britons. Oak forests in the time of the Saxons were much prized, chiefly for the fruit, which was useful for fattening hogs, the flesh of which was the principal food of the people at that time, a circumstance attributable to the great rapidity with which the hog multiplies his species, and the little preparation required for its maintenance.

2687. The fattening of hogs upon acorns was, among the Saxons, considered as an important part of domestic economy. Droves of swine were fed in the woods, particularly in the New Forest of Hampshire and the Wealds of Sussex. This right which the people enjoyed was called *pannage;* and the being deprived of it by William the Norman, who had a passion for converting all the forests into hunting-grounds, was one of the public grievances which was redressed by Magna Charta. The name is Saxon, *æcern* signifying corn of the oak.

2688. *The taste of common acorns is rough and disagreeable*, and they are astringent and difficult of digestion; even the hogs who feed upon them should go at large, and not be confined to the stye. Notwithstanding this objectionable quality, they have, in times of famine or great scarcity, been dried, ground into meal, and baked as bread in this country as well as in France, and it is said that they are still used in Norway and Sweden; but they are there first boiled in water, and mixed with one half or one third of corn flour, in which case they supply a nutritious food. Acorns are eaten at present in Spain, where they were long considered as a great delicacy, and even brought to the dessert. Cervantes often mentions them in his Don Quixote; but the Spanish acorns are sweeter than those of England. Some of the South American oaks produce acorns which are mild and nutritive. Acorns have been tried as a substitute for coffee, roasted, and having a little butter added to represent the oil in coffee; but they are not recommendable.

SECT. VII.—BERRIES.

2689. The name of berry (*Bacca*) is given to certain small fruits which consist of a pericarpium or skin full of juice or pulp, and seeds disposed throughout the pulp without any membranous capsule or covering. Almost all of those which we use as food grow upon shrubs cultivated in gardens, or are found wild on mountains or heaths. The most useful among them are the gooseberry, the currant, the raspberry, cranberry, and barberry, to which may be added the strawberry.

SUBSECT. 1.—*Gooseberry* (*Ribes Grossularia*, Linn.).

2690. This is perhaps the most useful of our fruits known by the name of berries. The best sorts form an excellent dessert fruit when ripe, and in their green or immature state they are employed in tarts, sauces, and creams. They are extremely useful when preserved, as they easily may be, throughout the winter. See Book X., Chap. IV., "Preservation of Food."

2691. The gooseberry is a native of cold climates, and is probably indigenous to these islands, or it has been long naturalized here, being found occasionally growing wild upon old walls, and in the woods and hedges in Cambridgeshire and Norfolk. It may be considered as peculiarly an English fruit, being produced in greater perfection here than in any part of the world. Foreigners are astonished at the size and flavour of this fruit among us. In Norway and Sweden the seasons are too rapid for its full development. The climate of Holland and some parts of Germany appear to suit it, and the pale kinds were first brought from Flanders in the time of Henry VIII. It grows wild in many parts of Europe, but the southern parts are too warm for it. Although it is found in Piedmont, the fruit is astringent and neglected. It is scarcely known in Italy and Spain, and in France it is little esteemed.

2692. *In its uncultivated state* it is a small berry, and it has been brought to its present state of perfection by the skill of English and Dutch gardeners; it may be easily raised in every cottage garden. The largest and finest in appearance are grown in Lancashire, where prizes are given for producing the largest; and the size of some shown upon these occasions is extraordinary, weighing an ounce or an ounce and a half. One gooseberry, exhibited in 1825, weighed 31 dwt. 16 grains; but the flavour of the very large sorts is inferior to that of the smaller kinds.

2693. *It would appear that the flavour improves with the coldness of the climate*, provided there be sufficient warmth to ripen them; for those grown in Scotland as far north as Aberdeen, and even Inverness, are of superior flavour.

2694. *There are numerous varieties of this fruit.* In vol. i., Series II., of the Transactions of the Horticultural Society, there is an account of seventy sorts, selected from those fruited in the Society's garden, and which were reckoned to have a good flavour, many of the large kinds having been rejected, their size not compensating for their coarseness. Some of the Lancashire growers enumerate above 300 sorts. The varieties are formed into four divisions, according to their colour when ripe, red, yellow, green, and white; and each of these again into hispid, downy, or smooth. The yellow gooseberries, in general, are sweeter, and have a more rich and vinous flavour than the white, which are often insipid. The green are sometimes extremely sweet, but generally inferior to the yellow, though sometimes very large. Of the red varieties, some are excellent, others rather acid; in short, every year produces new varieties, so that it is difficult to speak definitely of their characters. Some of them are early, and others late; of the latter, the variety called the *Pitmanston green-gage* is particularly deserving of notice, and in some seasons will hang till it shrivels, and almost candies on the tree. Gooseberries are not only very easily cultivated, but are, perhaps, the most wholesome of our fruits; and besides their use in the ordinary way, they are employed successfully for making excellent wine, which sparkles when the cork is drawn, and, when well made, is nearly equal to Champagne, and often passes for it. They are the earliest, as well as one of the best fruits for spring tarts, and are very easily preserved in the green state through the winter, so as to retain their natural flavour for tarts, cream, &c.; and when ripe, and preserved with sugar, they make excellent jams and jellies. From gooseberries being so useful for many purposes, both in a green and mature state, care is taken by the gardeners to have a succession of them through the summer months. The early sorts gathered green for tarts are to be had in April, or early in May, and until August. Some are ripe in June, and ripe gooseberries of a late sort are kept on the trees till September.

2695. *The pleasant acidulous flavour of the gooseberry is owing to the presence of malic and citric acid blended with sugar;* and upon the varied proportions in which these two principles are developed depends the fitness of the several varieties for dessert or kitchen use, for preserving, or for making wine.

Gooseberries and currants contain a large proportion of what has been named by chemists *pectic acid*, remarkable for forming the gelatinous coagulum when mixed with water, well known by the name of *jelly*.

2696. *The term gooseberry is supposed* to be a corruption of *grossberry*, the name among the ancient Latins being *grossulariæ*, from their resemblance to small unripe figs, or *grossi;* whence, also, the French *groseilles*.

2697. *The acid of gooseberries* may be procured in a separate form, the method of which is a late discovery by a French chemist. He ferments the gooseberry juice, distils off ardent spirit from it, which he reserves; the residual liquor he saturates with chalk, washes the insoluble powder thus produced, treats it with sulphuric acid, as in the process for extracting the crystallized lemons, filters off the liquor, and evaporates it, so that the crystals will form on cooling. By this mode 100 parts of gooseberries afford 10 of spirit, and 1 of crystallized acid, which is said to resemble citric acid.

Subsect. 2.—*Red and White Currants* (*Ribes Rubrum*, Linn.).

2698. Both these are considered to be varieties of the same species, since the berries in their wild state are all red, and it is cultivation that has produced the white and pale red varieties. There is little doubt that this elegant fruit is an improved native of Britain, being found wild (*Ribes sylvestre*) in many places. It has been supposed, however, that it has degenerated from the seedless grape of the Levant, still imported under the same name, currants. It is scarcely known in France, where it is distinguished from the gooseberry only by the name *groseilles en grappes*.

2699. *The white is preferred for the dessert*, being peculiarly juicy and cooling: they are best also for making wine. It is observed that all the white fruits of the berry kind are sweeter than the coloured, but other fruits that are coloured are generally sweeter than the white. Red currants are imported from Holland, and sold in Covent Garden market, after ours are out of season, at as low prices as our own. They are carefully packed in baskets of 15 or 20 lbs., and they consist only of large dry bunches, which keep better than ours. The red is used for tarts and in the preparation of jellies, and they are particularly useful, being easily preserved during the winter in bottles. Currants are not difficult to cultivate, and, being very hardy, they come within the attainment of every cottager who has a garden; when they are trained against the walls of the cottage they have an elegant appearance, not unlike that of the vine. Like gooseberries, they owe their pleasant flavour to the sugar and malic and pectic acids which they contain.

SUBSECT. 3.—*Black Currant* (*Ribes Nigrum*, Linn.).

2700. *The black currant is a distinct species*, is a native of most parts of Northern Europe, and is certainly indigenous in Britain, being found growing wild in woods, wet hedges, and other moist situations. The fruit, which has a peculiar flavour disliked by some, is occasionally, though seldom, brought to the dessert, but is eaten in puddings and tarts, and made into jelly, which is supposed to have a medicinal quality, and is used for hoarseness and sore throats. In Russia, where it grows in great abundance, and of a large size, they make a wine from it, and it is put into brandy, as cherries are in England: in Ireland it is put into whiskey. Cottagers in England, as in Siberia, sometimes mix the dried leaves of the tree with black tea, which gives nearly the flavour of a mixture with green tea; and it is suspected that tea is sometimes adulterated in this manner. When trained against a wall the berries grow to an extraordinary size. The varieties called the *black Naples* and the *black grape* are excellent for the dessert.

SUBSECT. 4.—*Raspberry* (*Rubus Idæus*, Linn.).

2701. This fruit derives its Linnæan appellation, "Idæus," from Mount Ida, where Pliny describes it to have grown. It was considered as a sort of bramble, though much improved by cultivation, and our name of raspberry is given to it from the rough spines with which the bush is covered.

2702. *There are two varieties*, the red and the white, both natives of Britain, and excellent for the dessert: the white is the sweetest. The flavour of the fruit is peculiar, but is very generally liked; it is, however, extremely volatile; even a few hours will diminish it, and, to be enjoyed in perfection, the fruit should be eaten off the bush. If kept for two or three days, the flavour will be almost entirely gone. The fruit is *sub-acid* and cooling, and the red is much used in tarts, and for jams, ices, &c. It also makes a delicious wine, and is employed for raspberry brandy and raspberry vinegar, a table spoonful of which in spring water makes a most refreshing beverage.

2703. Vast quantities are cultivated in the neighbourhood of Isleworth and Brentford, whence they are brought to Covent Garden market.

SUBSECT. 5.—*Strawberry* (*Fragaria Vesca*, Linn.).

2704. *The name of this favourite fruit* is said to be derived from an ancient custom of putting straw beneath the fruit when it began to ripen, which is now little attended to, but which is very useful to keep it moist and clean. The strawberry belongs to temperate and rather cold climates, and no fruit of these latitudes that ripens without the aid of artificial heat is at all comparable with it in point of flavour. The strawberry is widely diffused, being found in most parts of the world, particularly in Europe and America.

2705. The fruit has a delicious fragrance, and is universally esteemed for its agreeable flavour. It possesses a peculiar advantage of not creating acidity when taken into the stomach. It is nutritious, and very wholesome, and may be safely eaten by gouty and rheumatic patients who have been forbidden the use of other fruit. In addition to its grateful flavour, it is sub-acid and cooling, which renders it particularly agreeable in summer. Strawberries may be eaten alone, or with sugar and cream, and physicians consider them not only as wholesome, but rank them among their pleasant remedies, particularly in feverish habits.

2706. *The varieties are extremely numerous, but the principal strawberries*, as the *scarlet* and *Chili*, have been brought from America two hundred years ago: of these the *pine* is most esteemed, and the *hautboy*, though generally excellent, is the most variable.

2707. *Strawberries ripen* from June to August and September; but the main crop is over in July. One variety, a small red strawberry, grows wild in our woods, and is mentioned as an article of ordinary consumption in the time of Henry VI. The fine aromatic flavour of this fruit is not very durable, and a slight shower will sometimes almost entirely destroy it; on this account it should be gathered in dry weather, and the same day when it is to be sent to table. The strawberry is a kind of rock plant, and grows best on artificial banks, composed partly of broken fragments of rock.

SUBSECT. 6.—*Mulberry* (*Morus*, Linn.).

2708. The mulberry-tree is a native of Asia, and has been always a most valuable tree to the Chinese and Persians for feeding their silk worms. There are several species.

2709. The *white mulberry* (*Morus alba*) is a delicate tree, though it grows well in Spain, Italy, and the south of France; the berries are light-coloured and insipid, but its leaves are the best for feeding the silk-worm. It is seldom cultivated in this country.

2710. The *black mulberry* (*Morus nigra*) is a larger and more hardy tree, and is very commonly grown in England: the fruit is a blackish-red, and its juice stains the hands a deep colour: it is excellent for making a peculiar wine.

2711. *Mulberries are brought to the dessert*, and are esteemed for their highly aromatic flavour, and their sub-acid nature. They are considered as cooling, laxative, and generally wholesome. This fruit was very highly esteemed by the Romans, who appear to have preferred it to every other. The mulberry-tree is stated to have been introduced into this country in 1548, being first planted at Sion House, where the original trees still thrive. The planting of them was much encouraged by King James I., about 1605; and considerable attempts were made at the time to rear silk-worms on a large scale, for the purpose of making silk; but these endeavours have always failed, the climate being scarcely warm enough.

SUBSECT. 7.—*Elderberry.*

2712. *The common elder-tree* (*Sambucus nigra*, Linn.) is a native of this country, and is found near wet ditches and old walls. The wine made from elderberries is too well known by families in the country to require any encomium; it is almost the only wine that the cottager can procure, and, when well made, is a most excellent and wholesome beverage. That made from the white elderberry resembles some rich grape wine. The young tender shoots are much relished as a pickle; and if a sirup be made from ripe elderberries, with a few bitter almonds, and added to brandy, it has all the flavour of the very best cherry brandy.

2713. Professor Martin observes that this tree contains a whole magazine of physic to rustic practitioners. An excellent healing ointment is made from the green inner bark, and also with the leaves and flowers. Infusions of the flowers promote cuticular secretion, and form a powerful sudorific. The juice of the inner bark is one of the best hydragogues. No quadruped will eat the leaves of this tree, which also drive away all insects, except the peculiar ones that feed upon them.

SUBSECT. 8.—*Barberry* (*Berberis Vulgaris*, Linn.).

2714. The barberry is found in woods, coppices, and hedges in England, and is a native. The flowers are small and beautiful, and, when they first appear, have a perfume like cowslips, but which change to a putrid and most disagreeable smell, particularly towards the commencement and at the decay of the flowers. The fruit is extremely acid and astringent, but is cooling, and is thought to create appetite, though seldom eaten. Conserves and jellies made of it are refreshing and strengthening to the stomach. Barberries are employed as pickles and for sirups, which are considered as medicinal. There are several kinds; the fruit of some have stones, and others are without.

SUBSECT. 9.—*Whortleberry* (*Vaccinium Myrtillus*, Linn.).

2715. This is called also the *hartleberry* and *bilberry*. It grows wild abundantly upon our heathy commons and uncultivated hills. It is plentiful in the north of Europe. It is found on Leith Hill in Surrey, also in Devon. The fruit is seldom brought to the London market, although much relished by some persons in tarts or cream, or made into jellies. There are several varieties: the purple are rather larger than juniper-berries, and are covered with a fine blue or purple powder, like the bloom of plums. They are seldom cultivated.

SUBSECT. 10.—*Cranberry* (*Vaccinium Uliginosum*, Linn.).

2716. This berry is a red variety of the whortle, and is much esteemed in tarts or with cream. It is scarcely cultivated in gardens, but grows wild plentifully in peaty bogs and marshes, particularly in Lincolnshire, Sussex, Cumberland, and other similar places in Britain; also in Scotland. Considerable quantities of fine fruit are also imported from Russia and Germany, packed in casks. A large sort is brought from North America, and is used by the London pastry-cooks for tarts; but this kind is inferior to the English cranberries. Some have been brought from New-Holland, of a superior flavour.

2717. Cranberries are considerably astringent, and are thought to restore the appetite; they have a peculiar grateful flavour, something like black currants. They are easily preserved by drying them a little in the sun, and stopping them close in dry bottles. They are so plentiful in Cumberland that they are sold by the cart-load. The fruit is sometimes fermented into an intoxicating liquor, and is put into whiskey to disguise its peculiar flavour. It is said to possess narcotic powers, and is therefore also used in beer. It makes an excellent jelly, preferable to that from currants, for venison.

2718. *In the Transactions of the Horticultural Society, Mr. Milne recommends the cultivation of this berry*, which is now only collected in its wild state. He observes that, both the British and American species may be grown with much advantage in numberless situations in this island, with little trouble, and on soils where few other useful plants will grow to advantage. Cottagers and others living in the neighbourhood of moors and heaths covered with soil suitable to their growth, might cultivate them with considerable profit for the market; and if they could not be consumed or disposed of in the neighbourhood, they might be sent to a great distance without the hazard of being spoiled. The American would be the easiest managed, and most productive for general use; but, as many prefer the flavour of the English cranberry, there would be also a demand for it, though at a higher price.

SUBSECT. 11.—*Blackberry*, or *Brambleberry* (*Rubus Fruticosus*, Linn.)

2719. This is a species of raspberry; it is the most common of our native berries, and it is found in almost every hedge, being rather annoying with its long training stems and sharp thorns. In Wales it grows to a large size, and, in a fine summer, is really an excellent fruit. The berries are slightly astringent, and are made into a jam useful in sore throats. They are occasionally used in tarts. The juice, mixed with raisin wine before it is fermented, will give it the colour, and much of the flavour of claret.

SUBSECT. 12.—*Dewberry* (*Rubus Cæsius*).

2720. Phillips, in his *Pomarium Britannica*, p. 71, says that this is a variety of the blackberry; the protuberances are larger and fewer in number than those of the common blackberry. It is generally found trailing on the banks of hedgerows or in hazel copses, seldom growing above a foot high. He observes, "that it is a berry of excellent flavour, and well deserving a place in cultivated grounds, as it must be equally beneficial to society that our native fruits should be improved, as well as that new varieties should be imported from climates that can give but little hope of their thriving without the aid of artificial heat."

SUBSECT. 13.—*Juniper-berry* (*Juniperus Communis*, Linn.).

2721. This is the fruit of the common juniper, which grows wild on our hills. They are round, of a blackish-purple colour: when chewed, they have, at first, a warm, sweetish, and afterward a bitter taste. In Sweden they are made into a conserve, and eaten at breakfast. In some places they are roasted, and used as a substitute for coffee. A volatile oil is contained in cells in the shell of the nut, and not in the fleshy part of the fruit, that has a close resemblance to oil of turpentine, and which is used to flavour gin, but the juniper-berries employed for this purpose are imported.

SUBSECT. 14.—*Service Berries.*

2722. These are the fruit of the *wild service-tree* (*Pyrus torminalis*), very common in the hedges and fields, but, though at present little known, they were more in use formerly. The country people in some places gather the bunches of berries, and hang them up in the air till they undergo an incipient putrefaction, in which state they possess a peculiar acid, astringent taste, and are considered as having cathartic properties. When mellowed by frost they have been used as food. The service-tree is a native of England, but is now seldom seen except planted as ornamental trees.

SECT. VIII. — EXOTIC FRUITS WHICH DO NOT RIPEN IN THE OPEN AIR IN ENGLAND, AND WHICH ARE ONLY CULTIVATED IN THE HOT-HOUSE.

2723. It does not enter into our plan to describe the vast number of fruits that are found in various parts of the world: the following are occasionally imported in a preserved state, or are sometimes cultivated in this country by the aid of artificial heat.

SUBSECT. 1.—*Pomegranate* (*Punica Granatum*, Linn.).

2724. The pomegranate, which derives its name from "*pomum granatum*," a kernelled apple, possesses, independently of its valuable qualities, great historical interest. We find it often mentioned in the Bible, where it is included in the fruits of Palestine, with the vine, the fig, the olive, and other "pleasant fruits." It likewise grows wild in Barbary. Pliny states that the Romans brought it from Carthage in the time of Sylla; hence its name, Punica. It was likewise well known to the ancient Greeks, and held in great esteem by them: the story of Proserpine is well known, who, having been carried off by Pluto, was prevented from returning to the earth in consequence of having tasted of this fruit in the Elysian Fields. They are frequently represented in ancient sculpture.

2725. *The fruit of the pomegranate-tree* is about the size and shape of an orange. The rind is coriaceous, of a reddish-yellow colour, having a very styptic taste; but the pulp is succulent, contained in cells divided by membranes, and crowded with seeds; the juice is of a pleasant acid taste, and particularly grateful and cooling in warm climates. It is said to assuage thirst in a degree quite peculiar to it, from its acid, which is full of "pleasant sweetness." All the rest of the plant is highly astringent. The bark has so much tannin that it is employed in Germany and other countries for making an imitation of Morocco leather, and the rind of the fruit will do instead of nut-galls for ink: it was also employed medicinally in ancient times, as it is still in some places at present.

2726. The pomegranate flourishes in the open air in the south of Europe; but in England, though it blossoms readily in the southern counties, the fruit requires a greenhouse to bring it to perfection. It was first brought to this country in 1548, during the reign of Henry VIII., and it was among the trees that fruited in the orange-house of Charles I. The tree sometimes attains the height of twenty feet, and is highly prized as an ornament on account of its beautiful scarlet blossoms, which are extremely fragrant. In the West Indies, where it has been planted, the fruit grows larger and finer-flavoured than in Europe. Its singular and beautiful appearance adds to the variety at the dessert.

SUBSECT. 2.—*Banana* (*Musa Sapientum*, Linn.).

2727. This fruit is very generally diffused over the torrid zone of the New World, and an immense portion of mankind subsist chiefly upon it, answering to them instead of the wheat, barley, and rye in Europe and Western Asia, and rice in India. The banana is not known in an uncultivated state: among the wildest tribes in South America, as well as in other places, it is propagated by suckers.

2728. *No individual plant in the vegetable kingdom produces so much nutriment in the same* *space of ground.* The fruit is from five to seven or eight inches long, and sometimes a foot in circumference. Each plant will produce from 160 to 180 fruit, which grow in a bunch, and each bunch weighs from 60 to 80 pounds. Humboldt has observed that a European is surprised to see the smallness of the plantation of bananas round an Indian hut, which is found sufficient to maintain the family. A cultivated space of only 1000 square feet will admit of 30 to 40 bananas, which, together, will annually produce 4000 pounds weight of fruit: a produce 133 times greater than could be obtained from the same space if covered with wheat, and 44 times greater than if occupied by potatoes.

2729. *The form of the fruit* is somewhat like that of the cucumber, but of a highly grateful flavour, less luscious than the plantain, and composing an extremely nutritive and healthy aliment: the stalks are marked with purple spots, whereas that of the plantain is entirely green.

The plantain is relished by all ranks of people in the West Indies, and is considered as preferable to bread in hot climates. Dr. Wright observes that no species of provision could supply its place; even wheaten bread would be less agreeable, and less capable of supporting the laborious negro, and enabling him to preserve his health. In America it is the custom to plant banana walks, which they extend as their family increases. Some or other of the plants are in bearing the whole year round. It is eaten raw, roasted, or boiled, and is made into fritters, preserves, and marmalades; and it is dried in the sun and preserved like figs. Meal is extracted from it by pounding. Sometimes, after making it into a paste, they squeeze it through a sieve, form the mass into loaves, which are dried in the sun, or baked in hot ashes, after having been previously wrapped up in leaves. The fermented juice also affords an excellent wine.

2730. Bananas have been fruited in England in a hot-house. When the building is lofty enough they form a magnificent appearance, equal, if not superior, to what they present in their native climes.

Fig. 517.

Perfectly ripe bananas were produced in the hot-houses of the Royal Caledonian Horticultural Society, in Edinburgh, and were sent up to the Lord Mayor of London for the banquet given to the present queen at Guildhall, but, from some cause or other, were neglected to be mentioned in the published report, although certainly the rarest dish on that occasion.

2731. *Plantain* (*Musa Paradisiaca*, Linn.).—This fruit (*fig.* 517) is allied to the banana, but is a native of the Old World, growing in India and Africa, from whence it was carried to the West Indies.

2732. The fruit of the plantain is about the size of ordinary cucumbers. When ripe, it turns yellow, is sweet, of a mealy substance, tasting something like the melon, luscious, and dissolving in the mouth. It is brought to table as dessert, raw, fried, or roasted. It is used also in tarts, or dried, or preserved as a sweetmeat, and is considered as the most wholesome of all confectionery. The fruit grows in clusters on the tree, which is of the palm tribe, rising with a single stem to the height of fifteen or twenty feet, and having leaves only at top, each of which is about six feet long and two feet broad. The whole spike and fruit often weigh forty or fifty pounds.

SUBSECT. 3.—*Mango* (*Mangifera Indica*, Linn.).

2733. The mango (*fig* 518) is one of the most grateful to Europeans of all the tropical fruits. It resembles a short, thick cucumber in form, and grows upon trees forty or fifty feet high: it has a thin skin, and, on removing this, the interior consists of a pulp which melts in the mouth with a cooling sweetness, and a delicious, aromatic, and sub-acidulous taste. It is sometimes cut into slices and eaten with wine, or is candied to preserve it. In the heart is a small stone. The mangoes of Asia are said to excel those of America.

Fig. 518.

2734. In India they are constantly at the dessert in the hot months, and no fruit is held in such high estimation; it is extremely wholesome and nutritious. The green fruit is made into jellies, conserves, tarts, &c. The ripe is very perishable, and cannot be brought to this country except pickled, from which no idea can be formed of their exquisite flavour: altogether, they are considered as one of the chief dainties of the vegetable world, and are, consequently, cultivated wherever the climate admits of it and the arts of civilization have penetrated. There are many varieties, some of which are ill-flavoured.

2735. By the Hindoos the wood of the tree is consecrated to the service of the dead, and used for coffins and funeral piles. From the flour of the dried kernels several kinds of food are prepared, and the stalks are employed with the betel nut.

2736. The mango has been fruited both in France and England. If a few *worked plants* could be had from Jamaica, and a stove fitted up for them, there is little doubt, according to Mr. Knight, that the fruit might be had upon the table as easily as the pineapple.

SUBSECT. 4.—*Mangostan* (*Garcinia Mangostana*).

2737. This (*fig.* 519) is one of the most delicious fruits in the world, and grows in Sumatra, Java, and other islands of the Indian Ocean. The fruit is about the size and shape of the orange, surrounded by a thin shell. The pulp is juicy, and of an exquisite flavour, partaking of that of the pineapple and strawberry, though some have compared it to other combinations of the best fruits. It is also very wholesome, and is almost the only fruit allowed to some invalids, being cooling, and a happy mixture of the tart and the sweet. The tree is about twenty feet high, and extremely beautiful.

Fig. 519.

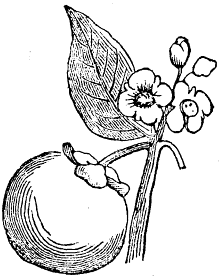


Fig. 520.

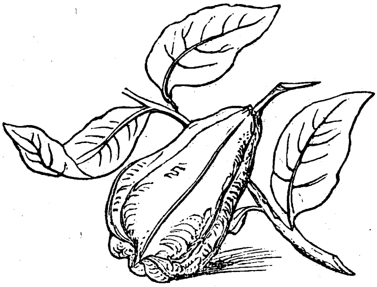


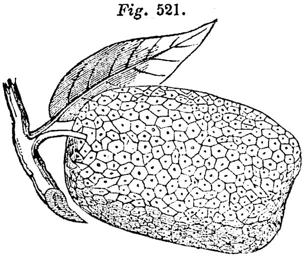
SUBSECT. 5.—*Aku* (*Blighia Sapida*, H. R.).

2738. This fruit (*fig.* 520) is so named because it was carried by Capt. Bligh, in 1793, from Guinea, its native country, to Jamaica, where it now grows well, and is much esteemed. The fruit is a pome, about the size of a goose's egg, having a grateful subacid flavour, and being very wholesome and nutritive. It has been planted in this country, and, it is thought, may, in a few years, produce fruit as easily as the orange.

SUBSECT. 6.—*Bread Fruit* (*Artocarpus*, Linn.).

2739. This very important fruit was originally found in the southeast parts of Asia, and the islands of the Pacific. There are two species of bread fruit, the *Artocarpus integrifolia*, with the leaves entire, which grows chiefly on the continent of Asia; and *A. incisa*, with the leaves deeply notched, which grows chiefly in the islands, and is the proper bread fruit (*fig.* 521). The first is called *Jaca*, and the fruit grows to an enormous size, often to more than 30 pounds. It is eaten, but it is not very palatable. The last, the proper bread fruit tree of the South Sea, was found originally in the islands of the Indian Ocean and Southern Pacific by Dampier, in 1688: it grows to the size of a middling oak, and the fruit is about eight or nine inches long, of a yellowish-green colour, and is covered with hexagonal warts. It grows in clusters of five or six. The pulp is white, and is partly farinaceous and partly fibrous: when quite ripe it becomes yellow and juicy.

Fig. 521.



2740. *It is dressed in various ways.* When roasted or baked, they scrape off the second rind, and the interior is eaten as bread; it has no seed nor stone. Its taste is agreeably sweet, between that of wheat bread and roasted chestnuts. It is extremely nutritive, but must be eaten new, for in twenty-four hours it becomes harsh and unpalatable. When boiled it much resembles potatoes; some think it more like the Jerusalem artichoke, and others the chestnut. It is also beaten up with cocoanut and milk. The fruit is gathered before it is fully ripe, for when mature it quickly runs into decay. The bread fruit continues in season above eight months in the year; and so productive is it, that two or three trees are sufficient for the yearly support of one person: during the remaining months they make of it a sourish paste, which they keep for store.

2741. *At the expense of this government, and through the well-known exertions of Captain Bligh,* the bread fruit has been brought to the West Indies in consequence of the great expectations that had been formed of its utility; but, though it is easily cultivated, it does not appear to excel the banana. From experiments made in the West Indies, it appears that it could be converted into flour, from which cakes were made extremely well flavoured. It is scarcely necessary to say that in this country it can only be raised in the hot-house.

SUBSECT. 7.—*The Durion* (*Durio Zibithinus*, Linn.).

2742. This is an Asiatic fruit which grows upon a lofty tree; and, though of an agreeable taste, has an unpleasant strong odour. Some of the fruits are as large as a man's head, and are covered with a kind of pointed scales. It must be eaten fresh, as it putrefies in twenty-four hours. The part which is eaten is a thick pulpy juice of the consistence of thick cream, which has the flavour of a delicate animal substance mixed with a cool vegetable acid. This singular flavour cannot be imitated by any process of cookery; and the substance is extremely nutritious. It is a costly fruit even in its native country, and is highly prized.

SUBSECT. 8.—*Guava* (*Psidium*).

2743. There are various species of the guava, some of which are natives of Asia, some of America, and some common to both. The best of these is the white guava (*Psidium pyriferum*), which is plentiful in the West Indies. The fruit is rather bigger than a hen's egg, yellow, smooth, and of a peculiar smell. The pulp is of a very agreeable taste, sweet, aromatic, and flesh-coloured. It is used at the dessert, and preserved. Guava jelly is considered as one of the finest conserves which we have from the West Indies.

SUBSECT. 9.—*The Mamma* (*Mammea Americana*).

2744. This is a native of the West Indies, where the tree grows to the height of seventy feet. The fruit is yellow, and somewhat resembling a russet apple in size and shape. The pulp is yellow, and is very fragrant and delicious, like the finest apricot.

SUBSECT. 10.—*The Litchi* (*Dimocarpus Litchi*).

2745. This is a Chinese fruit, round, and about two inches and a half in diameter. It is covered with a tough leathery coat, within which is the pulp, colourless, semi-transparent, slightly sweet, and of a very agreeable taste. It is often brought to this country in a dried state, in which, though the pulp be much diminished in size, it retains a considerable portion of its original flavour. It is not unlikely but it may become common in this country as a hot-house fruit.

SUBSECT. 11.—*Jujube* (*Zizyphus Vulgaris, Z. Jujuba*).

2746. This is a favourite dessert fruit in Italy and Spain, either fresh, or dried as a sweetmeat; and a pleasant pectoral lozenge is made of it by the French apothecaries. The fruit is to be seen in abundance in the markets of Constantinople and the southern parts of Europe: the Turks plant the trees round their coffee-houses, that they may enjoy both their shade and their fruit. It is found in greatest perfection in China, where there are upward of sixty species.

SUBSECT. 12.—*The Juvia* (*Bertholletia Excelsa*).

2747. This fruit is described by Humboldt as that which encloses the triangular grains imported under the name of *Brazil nuts*. The fruit itself is as large as a child's head, being covered by a shell, and growing upon a tree fifty or sixty feet high; the force of their fall is so great as to be fatal to one who might be struck with them; hence the Indians never enter the woods where they grow, in the season of fall, without covering their heads by a buckler.

SUBSECT. 13.—*Papau* (*Carica Papaya*).

2748. The papau, which resembles a gourd, about the size of an ordinary melon, grows on a branchless tree in the East and West Indies. It is cultivated, and is eaten both raw and cooked. It is wholesome, but not very palatable. It is usually gathered when half grown, and soaked in water to withdraw an acrid milk like mangoes, for which it sometimes forms a substitute. The milk of this fruit is a singular substance, for it contains a large proportion of a species of fibrin, very like that of animal flesh, and that of fungi, a circumstance which is uncommon among vegetables; and the exhalations from the leaves of the tree have so powerful an effect, that newly-killed meat suspended on the tree in a few hours becomes quite tender; and the flesh of old hogs and poultry fed upon the leaves are said to be as tender as that of young pigs and pullets.

SUBSECT. 14.—*The Alligator, or Avocado Pear* (*Laurus Persica*).

2749. This is another West Indian fruit, about the size of an apple. It is considered as one of the most delicious of fruits. It consists of a kernel enclosed in a soft rind, and the yellow pulp has the firmness and delicate flavour of the peach, but much superior.

SUBSECT. 15.—*The Anchovy Pear* (*Grias Cauliflora*).

2750. It is, likewise, one of the fruits of the West Indian islands. It much resembles the mango in taste, and when green is sometimes pickled. It might be raised in England like the pineapple.

CHAPTER X.

SPICES.

SECT. I.—GENERAL REMARKS.

2751. *All the substances classed as spices are the produce of tropical climates only*; none of our native plants, and no plants that come to maturity in the open air in this climate, possess sufficient aromatic flavour to be reckoned among the spices. The most valuable of these natural productions were originally found in the islands situated in the Indian Ocean, called the Spice Islands, or Moluccas, and were probably conveyed from them in the most distant ages. The spices which Queen Sheba presented to Solomon were unknown in Palestine, and probably came from Ceylon or some of the islands to the east.

The delicious aromatics of tropical regions were highly prized by the ancient nations; and, besides spices, we read of frankincense and myrrh, from the East, as ranking among their most esteemed luxuries. The wealthy Romans indulged in these to an extravagant degree; as navigation and the means of intercourse between distant nations improved, from the facility of transport, they found their way, as articles of traffic, to countries very remote from the places of their production; and the inhabitants even of the northern parts of Europe shared in the advantages of this commercial spirit.

2752. *On the use of foreign spices*, we may quote Dr. Paris in his work "On Diet." "These were not," he observes, "intended by nature for the inhabitants of temperate climes: they are heating and highly stimulant. I am, however, not anxious to give more weight to this objection than it deserves. Man is no longer the child of nature, nor the passive inhabitant of any particular region: he ranges over every part of the globe, and elicits nourishment from the productions of every climate. It may be, therefore, necessary that he should accompany the ingestion of foreign aliment with foreign condiment. Nature is very kind in favouring the growth of those productions which are most likely to answer our local wants. Those climates, for instance, which engender endemic diseases are, in general, congenial to the growth of the plants that operate as antidotes to them. But if we go to the East for tea, there is no reason why we should not go to the West for sugar. The dyspeptic invalid, however, should be cautious in their use; they may afford temporary benefit at the expense of permanent mischief. It has been well said that the best quality of spices is to stimulate the appetite, and their worst to destroy, by insensible degrees, the tone of the stomach. The intrinsic goodness of meats should always be suspected when they require spicy seasoning to compensate for their natural want of sapidity."

Sect. II.—pepper (*Piper*, Linn.).

2753. This is a well-known spice of an aromatic odour, and an extremely pungent and acrid taste.

2754. *Black Pepper* (*Piper nigrum*, Linn.) is the fruit of a species of climbing vine, a native of the East Indies, and found on the slopes of mountains in the southern parts of both peninsulas; it is also cultivated extensively in Malabar, and the eastern islands, Sumatra, Java, Borneo, and those which are near. It was formerly known only as the growth of these countries, the whole globe being supplied from them; but it has been lately introduced into Cayenne. The berries grow in spikes of from twenty to thirty, are at first green, and when ripe they are of a bright red colour. After being gathered, which they are while green, they are spread out on mats, with their skins on, and dried in the sun: thus they become black, and more or less shrivelled. Those which are least ripe, and in the fittest state for gathering, shrivel the least; but when they are more ripe, they often shrivel up entirely, or contain nothing but dust. The goodness of pepper is tried by rubbing it between the hands, and what is easily reduced to powder is unsound and bad.

2755. *White Pepper* is not the produce of a separate plant, as was once supposed, but is made from the black, by steeping it in lime and water and rubbing it between the hands till the coats come off, the powerful acrid oil residing chiefly in the skins. As it is only the best grain that will bear this operation, the white pepper is the superior kind, and fetches a higher price; it is, of course, milder than the black, and is much prized in China, but little of it is brought to England. Pepper is sometimes sold in the shops ground, and then it is often sophisticated, the black with burned bread, and the white with rice flour.

2756. Pepper is very generally employed as a condiment, and, from its promoting the secretion of the gastric juice, it aids the digestive powers of the stomach, sometimes rendered necessary in our artificial mode of living; but, even in small quantities, it is hurtful in inflammatory habits. The quantity of pepper imported into Europe is quite enormous.

2757. According to the analysis of Pelletier, pepper contains a peculiar substance called *piperina*, a concrete acrid oil, a volatile oil, starch, malic and uric acids, and lignin. The oil of pepper is too pungent to be tasted; applied to the skin, it reddens and inflames it: from which we may comprehend the effect upon the palate and stomach.

2758. *Long Pepper* is produced by a different plant (*Piper longum*), growing in the same countries. It is less aromatic than the black, but the oil is still more pungent.

2759. *Cayenne Pepper* is a very different substance, and is the most heating and stimulating spice with which we are acquainted, being extremely pungent and acrid, setting the mouth, as it were, on fire. It is powder prepared from several varieties of the capsicum, which are annual plants, natives of both the Indies, where they are used in large quantities both with vegetable and animal food, and from these countries we have borrowed their use.

There are three varieties of capsicum, all natives of tropical climates, but which have been so far naturalized in this country as to bear in the open air in summer. *Guinea pepper* (*C. annum*) was introduced into England from India so early as 1548. The plant rises about two feet, and has white flowers succeeded by pods, which, when ripe, are yellow or red. *Cherry pepper* (*C. cerasiforme*) was brought from the West Indies in 1759. It is very like the last, only its pods are generally round, like cherries. *Bell pepper* (*C. grossum*) produces the largest pods, and is, therefore, generally preferred. The pods of all these, when ripe, are extremely hot in their taste; and when in their green state they are used as a pickle, and called *chillies* with us. When ripe, they are ground into the condiment called *Cayenne pepper;* but the best of this we have from the West Indies ready prepared, and it is made from the *C. baccatum*, or *bird pepper*, so called because much eaten by birds, as hens and turkeys, which are extremely fond of it. The East Indian Cayenne is prepared in a very careless manner, and has often a dirty brown colour. To improve the colour, by making it red, a colouring substance is sometimes added, and Accum has stated that he had detected red-lead, which is a poison. With us, capsicums, or chillies, are ripe in September or October, and the pods are easily pounded in a mortar, after being dried before the fire. They may be purchased in Covent Garden market. About one fourth their weight of salt is mixed with them in the mortar to prevent the dust getting to the eyes. Dr. Kitchener states that this is the only way to have genuine Cayenne, and that the English has a finer flavour than the foreign, though not half the heat.

2760. *This powerful spice has become a necessary article at table*, and is much esteemed for its flavour, and the quality which it is supposed to possess of promoting the digestion of fish and other kinds of food. But it may be doubtful if the practice is conducive to health; for, though Cayenne pepper, like highly-flavoured Indian soys, may occasionally assist digestion, it would, perhaps, be better that invalids should abstain from food requiring a vigorous stomach, than to employ artificial stimulants.

2761. The dish called *Man-dran* in the West Indies, which is resorted to for exciting an appetite, and which is said to be sure to do so in the most languid state of the digestive organs, is a mixture of bird pepper, shallots or onions cut small, a little lime juice, Madeira wine, and sliced cucumbers.

Sect. III.—cinnamon (*Laurus Cinnamomum*, Linn.).

2762. This is the inner bark of a tree, a native of Ceylon, and several countries in the East, as China, Borneo, &c., but it is now cultivated in the West Indies and South America. It has also been lately planted in Egypt, and appears to succeed. The cinnamon-tree grows to the height of twenty feet; but when cultivated for the sake of the spice it is not allowed to attain its full size, but is lopped close to the ground when about ten feet high, with a stem one or two inches in diameter. New branches shoot up from the roots, and these shoots are cut when from half an inch to three quarters of an inch in thickness, and in length from two to three feet. The fragrant bark is protected by a tasteless cuticle, and after this is stripped off the bark is dried, which makes it shrivel up and assume the quill form in which it is imported, and the smaller pieces are put within the larger. The best is scarcely thicker than paper, and in long pieces, of a light yellow, bordering upon fawn brown, a dark colour being a mark of inferiority. Its odour is very fragrant; its taste is agreeable and highly aromatic, hot, but not too pungent to be borne upon the tongue, and without any bitterness.

2763. Cinnamon easily communicates its agreeable flavour to any other substance, and hence it is much employed in the most delicate preparations of the cook and confectioner.

2764. An essential oil is distilled from it in the countries where it grows; but very little of this is contained in the bark as we have it. This oil is very pungent, and is heavier than water; it is extremely dear. The best cinnamon comes from Ceylon, where a greater quantity grows than in any other part of the world; and the property of all the cinnamon-trees there is retained by our government, though the regulations by which the preparation of their produce for market was limited and restricted are now relaxed: some of the Chinese is also very good, but generally it is inferior; the Cayenne is thicker, but not so good; that from Brazil is the worst.

2765. *Cassia is a bark* brought chiefly from China and Ceylon, possessed of the usual properties of cinnamon, and was once supposed to be the produce of another tree; but it is now certain, from the observations of Mr. Marshall, that it is only the bark from the trunk and larger branches of the cinnamon-tree: it is of a flat shape, much thicker, and has the mucous integument of the bark remaining, which is cleared off from the proper cinnamon. It has the same qualities of cinnamon, only in an inferior degree. According to Vauquelin, cinnamon contains volatile oil, tannin, mucilage, a vegeto-animal colouring matter, an acid, and woody fibre. The oil of cinnamon is prepared chiefly from cassia and from the chips of cinnamon: eighty pounds yield about two ounces and a half of the oil, worth in England a guinea per ounce.

Sect. IV.—cloves (*Eugenia Caryophillata*).

2766. Cloves are the fruit, or, rather, the calyx of the unexpanded flowers of the clove-tree. Their name in French is *clou*, a nail, from their resemblance to one, and hence our term "clove."

2767. The tree is a native of the Malacca Islands, where they were originally found by the Portuguese in 1511, the date of their introduction into Europe. The Dutch, on gaining possession of the Spice Islands, endeavoured to secure a monopoly of cloves; and with the view of confining the cultivation of the tree to Amboyna, the seat of their power, they bribed the surrounding chiefs to cut down all the clove-trees in the other islands. As these contracts still exist, a military officer with a party of soldiers annually visit every place with axes to destroy the young trees, which spring up in astonishing abundance. Sir Stamford Raffles describes the clove as a tree of noble height, somewhat like the bay, and composing, by the beauty of their form, the luxuriance of their foliage, and the spicy fragrance with which they perfume the air, some of the most delightful objects in the world. The best variety of the Amboyna clove, called the *royal clove*, is scarce. It is smaller and blacker than the other kinds.

2768. But, notwithstanding this conduct of the Dutch, cloves are now cultivated in other parts of the world. The French introduced them at Mauritius, Bourbon, Cayenne, and Martinique, and they have since been carried to St. Kitt's, St. Vincent's, and Trinidad. The trees live twenty-four years, and bear from six to twenty years. After the cloves are collected in the green state, they are dried quickly by exposure to heat and smoke, until they appear of a deep brown colour; after which the drying is completed in the sun. Those dried wholly in the sun are the best.

2769. *Cloves form one of the most agreeable of all the spices*, and are much employed in flavouring many dishes, preserves, liqueurs, &c. They contain a considerable quantity of essential oil of a very pungent quality, in which their efficiency consists, and this is procured by distillation; it is said that the Dutch sometimes extract part of this oil, and then mix the deteriorated cloves with fresh ones, from which they imbibe some of what they contain. Cloves are also very liable to imbibe water, which increases their weight.

2770. *Cloves are employed* more for their flavour than for their medicinal qualities; but they are likewise very powerful stimulants of the stomach, and are used, but with caution, in conjunction with bitters. They yield their medicinal and other qualities to water and to alcohol.

2771. *According to Tromsdorff, 1000 parts of cloves contain* 180 of volatile oil; 40 extract scarcely soluble; 130 gum; 60 resin; 280 woody fibre; and 180 water. The volatile oil of cloves might be advantageously employed instead of the dried clove in culinary processes.

Sect. V.—nutmeg (*Myristica Moschata*).

2772. This is also a native of the Spice Islands, the Moluccas, and the monopolizing spirit of the Dutch was long enabled to keep the cultivation of it to themselves by extirpating it from all the islands except Banda, where it is chifly grown, the whole of the plantations being in the possession of their government. But while the English had possession of the Spice Islands, plants were carried to Penang and Bencoolen, where they now flourish, and produce a considerable quantity of nutmegs. Sir Stamford Raffles states that they are also largely cultivated in Sumatra. Attempts have likewise been made to introduce them into the West Indies, not altogether without success. The tree is not unlike the pear. It bears fruit all the year round.

2773. *The exterior part of the fruit is a pulpy substance*, sometimes brought to table in India as a preserve; within this is a thin shining black shell surrounded by membranous layers, which constitute another of our spices, the *Mace*, and within the shell is the nutmeg. To prepare them, the pulp is cleared off, and the mace separated by a knife; the nuts are then dried in the sun, and afterward by the fire; by this the shell becomes brittle, and the kernel within shrinks, which admits of the nuts being broken without injuring the nutmeg. They are then soaked in sea water, and impregnated with lime to destroy the vegetating power and keep away insects; but Mr. Crawford observes that the natives, if left to themselves, transport them in the shell, which is by far the best mode.

2774. *There are two sorts of nutmeg;* one wild, which is long or oval-shaped, and much inferior: the cultivated nutmeg is nearly round: the best are firm, hard, and of an unctuous consistence, the odour strong, aromatic, and agreeable; taste hot and acrid. When cut across, they appear full of dark veins, which contain much volatile oil.

2775. *This oil is yielded by distillation*, and it possesses the flavour of the nutmeg in perfection, two drops being nearly equal to a pound of the powder; this is made from the broken kernels; and it is said that the nutmegs are sometimes punctured and boiled for the purpose of extracting the oil, the holes being filled up with sassafras: *it is* one of the few oils of tropical climates that are lighter than water. It is employed in medicine.

2776. *The nutmeg is much used as a condiment;* but Dr. A. Thomson observes that, if taken in large quantity, it is found to have narcotic effects, and to produce symptoms indicating great determination to the head, on which account it should be cautiously used in apoplectic and paralytic habits.

2777. *The analysis of M. Bonastre shows nutmeg to contain*, in 100 parts, 24 of an insoluble white matter (stearin); 7·6 of an insoluble coloured butter (elain); 6·2 of a volatile oil; 0·6 of an acid; 2·4 of fecula; 1·2 of gum; and 58·0 of ligneous matter.

Sect. VI.—mace.

2778. ***Mace is the reddish membrane surrounding the shell which contains the nutmeg.*** It is dried previous to packing tight in bags. Its general qualities are the same as those of nutmeg; it has an agreeable aromatic odour, and a hot, biting taste. According to Mr. Henry, it contains a small quantity of volatile oil; a large quantity of a yellow, odorous, fixed oil, soluble in ether, but insoluble even in boiling achohol; a nearly equal quantity of a red, odorous, fixed oil, soluble both in ether and alcohol; a gummy matter forming nearly a third of the weight of the mace; and a small quantity of woody matter.

Sect. VII.—ginger (*Zingiber Officinale*, Linn.).

2779. Ginger is the tuber, or, rather, the rhizome, of a plant which is a native of the mountain of Gingi in Hindostan, whence the name. It was carried from India to Cayenne and the West Indies, where the greatest part of the ginger of Europe is cultivated. There are two kinds of ginger, but the difference consists chiefly in the mode of preparing it. *White* ginger consists of the best pieces, of which the outer skin has been scraped off; they are then well washed and dried in the sun: it breaks with a fibrous fracture, and is the strongest and best flavoured: good ginger should be compact and heavy. *Black* ginger is the inferior kind, which has only been scalded before it was dried.

2780. Ginger is one of the most agreeable and wholesome spices: it is much used in culinary operations, and likewise in beer and other beverages. It is stimulating to the digestive organs, and is less hurtful than pepper; but, like all excitants, it should be used with great moderation. The constant use of any kind of spices is, as we have stated, to lessen in time the nervous irritability and weaken the digestive function; for this reason, gingerbread, which contains a great deal of ginger, is very injurious to the stomachs of children. As a medicine it is occasionally highly useful; and an essence or essential oil of ginger is prepared as a more convenient mode of applying it.

2781. *Preserved ginger* comes to us from the West Indies. It is made by scalding the roots when they are green and full of sap; then peeling them in cold water, and putting them into jars with a rich sirup, in which state we receive them. It should be chosen of a bright yellow colour, with a little transparency: what is dark-coloured, fibrous, and stringy is not good.

Ginger roots, fit for preserving, and in size equal to West Indian, have been produced in the Royal Caledonian Horticultural Garden in Edinburgh.

When analyzed, ginger is found to consist chiefly of starch; besides which it contains a resin soluble in ether, another insoluble, a volatile oil, a vegeto-amimal matter, acetic acid, potash, gum, sulphur, and lignin. The pungency consists in the oleo-resin combined with the starch.

Sect. VIII.—allspice, pimento, or jamaica pepper (*Eugenia Pimenta*, Linn.).

2782. This well-known and useful spice is the berry of a handsome tree that grows to the height of twenty feet in the West Indies and South America. It belongs to the natural order of the Myrtaceæ, and as it grows spontaneously in Jamaica, the seeds are supposed to be sown by birds. The fruit is not suffered to ripen, but is gathered while yet green; when dried in the sun it becomes black. It is less expensive than the Oriental spices, and, as it combines the flavour of cinnamon, nutmeg, and cloves, it is known here popularly by the name of *allspice*. It is a very agreeable aromatic, and is considered as the most mild and innocent of the common spices; hence it is much employed for domestic purposes.

Its active principle resides in an essential oil, which it gives out readily to water and spirit. The essential oil, or essence of allspice, is of a deep reddish-brown colour, and extremely pungent; a few drops is sufficient to give a flavour to gravy, or to mulled wine.

The best pimento is from Jamaica; an inferior and larger kind grows in Tobago.

It may be proper to observe that it is the practice of London shops to sell what they call *mixed spice*, which consists of a portion of all the above-mentioned spices ground together; this is much used about Christmas time, and is convenient for many purposes.

Sect. IX.—lemon and orange peel.

2783. *Among the aromatic condiments may likewise be reckoned the rinds of the lemon and orange*, called lemon and orange peel, which owe their high flavour to the essential oil they contain, which is extracted and sold as the essence of lemons and oranges; a few drops of this essential oil is equally efficacious with the peel itself, and has the advantage of being easily preserved, whereas the peel, when dried, loses most of its flavour in time, from the essential oil escaping.

BOOK VIII.

ON THE VARIOUS BEVERAGES USED IN THE BRITISH ISLES

CHAPTER I.

WATER.

SECT. I—INTRODUCTORY OBSERVATIONS.

2784. In the following account of water, we propose to confine ourselves chiefly to the consideration of those properties which relate to its use as a beverage, either alone, or as an ingredient in the preparation of the various kinds of drink which we shall describe; and to its employment in the culinary art.

2785. *As a beverage, the qualities of water differ materially;* every one is sensible of the great difference between that of a soft and clear spring, and that of a stagnant pool; and persons much accustomed to this simple beverage can distinguish flavours in it which are not sensible to others. The value of purity in water is universally admitted, but it requires to be explained in what that purity consists; for it can be shown that water absolutely pure is not the fittest for many purposes. All water, in a natural state, is impregnated with a certain proportion of air, which is highly useful; and of many other substances found more or less in water, some are harmless, while others are extremely prejudicial.

2786. *The most general distinction of water is into hard and soft,* and both the cook and the laundress may practically be good judges of these properties; yet we do not consider it sufficient to possess this merely practical knowledge; we shall therefore enter more minutely into the natural history and details respecting a liquid in such universal use, and of such serious importance to the health and comfort of families.

2787. With this view, we propose first to inquire into the chemical nature of water as a liquid body, and we will afterward examine the properties of the several kinds which are obtained from different sources, and which are found in various situations in the earth; to which will be added instructions as to the best modes of supplying and preserving it.

SECT. II.—OF THE COMPOSITION AND GENERAL PROPERTIES OF WATER.

2788. In order to have a clear idea of the nature of water, we must take a view of its *chemical constitution.*

2789. *Water was long considered as one of the natural elements,* and, consequently, was supposed to be simple, and incapable of being decomposed, or separated into other substances. The discoveries of chemistry, however, have proved that this fluid is, in fact, a chemical combination of two kinds of gas, or air, which, of themselves, are invisible. The nature of these gases has been mentioned in Book III., "On Ventilation;" but as a certain degree of repetition is unavoidable in a work like the present, it will be proper to speak of them again as the elements of water.

2790. *The two gases of which water is composed are oxygen and hydrogen.* Oxygen is that gas which we formerly stated to enter into the composition of the atmosphere which we breathe, and without which, indeed, life could not be supported; hydrogen is an inflammable body, and is the basis of the gas now so much employed in lighting our streets. But water is *not a mere mechanical mixture* of these two kinds of air, for if a portion of each of them be merely introduced into one vessel, water will not be the result. In order to produce the fluid we are treating of, these gases must be *united* in what is termed a *chemical* mode, that is, by a particular and intimate union very different from simple mixture. There is no doubt that water is thus formed daily by many natural processes, some of which are connected with meteorological phenomena. The fact of the composition of water was first shown by Mr. Cavendish, who demonstrated it by *burning* oxygen and hydrogen gases in a dry glass vessel, by which a quantity of pure water was generated exactly equal in weight to that of the gases which had disappeared.

2791. *By ingenious experiments, water can be separated into its elementary constituents,* oxygen and hydrogen; and by another process these very constituents can be made to re-unite, and form the same quantity of water as was decomposed. There is, therefore, no opinion in natural philosophy better established than that water is a compound body, and, consequently, that it cannot be ranked among the elements.

When we speak of the general properties of water as a body, we allude only to water which is absolutely pure, and unmixed with any other matter whatever.

2792. *Although pure water is composed of two gaseous bodies, yet there is no variety in its composition;* that is, a given quantity of water has not at one time more oxygen, and at another more hydrogen, but the proportion of these constituents is always precisely the same, namely, eight parts, by weight, of oxygen, and one of hydrogen. Neither is pure water, in itself, liable to any change whatever; when its elements have once fairly united to form a liquid, they cannot be separated or altered in any manner without the liquid entirely losing all its properties; in short, by no longer existing as water. Why, then, it may be asked, do we hear of different kinds of water? If water be unchangeable, what distinctions can be made, or how can various specimens of water have different qualities, as hard, soft, and so on? The answer to these questions will form the subject of the following pages. And first we shall describe the properties of water as a body, independently of every kind of mixture with any other substance, or contaminations of any kind.

2793. *Water is volatile*, that is, it is capable of being converted into vapour. If a vessel containing water be exposed to the air, the water gradually lessens in quantity, and, at length, disappears altogether. This, in familiar language, is said to be the *drying up* of the water; but the fact is, the water has insensibly been converted into invisible vapour, which has mingled with the atmosphere. This is called *evaporation;* not a particle of the water is lost, but the whole has dissolved in the air, to return one day in the form of rain.

2794. *We have already shown* (in Chap. I., Book I., "On Heat") that water boils, or is converted into steam, when it is heated to 212° in the ordinary pressure of the atmosphere, that is, when the barometer stands at 30 inches; water cannot be made any hotter in open vessels, because the steam carries off the heat. If salt be added to water, it is capable of being heated to a degree higher than 212°, in proportion to the strength of the brine.

2795. *But water may be heated to a much higher degree in closed vessels*, where the steam is confined so as to exert a great pressure upon the surface of the water; or the steam may thus be prevented from forming; but in that case it is requisite that the vessels should be extremely strong, or have a safety-valve, otherwise there is danger of their bursting. The digesters for dissolving meat and bones are made upon this principle.

2796. We may here refer the reader to what we have said in Chap. I., Book I., "On Heat," for many details connected with the heating of water.

2797. *Steam is condensed again into water by cold:* if deprived of the heat which made it steam, it returns to its former liquid state. On these two processes, the conversion of liquids into the elastic form, and condensing them by means of cold into the liquid form again, the *art of distilling* depends.

2798. *Water is so bad a conductor of heat* that it was supposed by Count Rumford to be absolutely a *non-conductor*. And although late experiments have shown that this is not actually the case, yet water conducts heat so imperfectly that the count's conclusion may be taken as true for practice in the greater number of ordinary cases. A vessel of water, when put upon the fire, is heated by the lower stratum of water expanding, and becoming specifically lighter; hence it ascends through the rest to the top, causing another layer to take its place; this becomes heated in its turn, and so the various particles of water *transport* or *carry* the heat upward by their motion.

2799. *Water becomes solid, or is converted into ice*, when it is cooled down to 32°, and the ice begins to be formed by appearing like needles crossing each other. In freezing, the air contained in water is excluded, but the bulk of the ice being greater than that of the water which has been frozen, ice is specifically lighter than water, and swims upon it. The specific gravity of ice is about 0·94; that is, it is $\frac{6}{100}$ lighter than water.

2800. *Water, in freezing, and increasing in bulk, expands with great force;* and hence it frequently bursts very strong vessels in which it may be contained: to this cause must be attributed the rupture of pipes in frosty weather. The expansive force of ice in freezing is well shown in an experiment made by Major Williams. A bomb-shell, thirteen inches in diameter, and more than two inches thick, was filled with water, and the fuse-hole plugged up with an iron bolt: thus charged, it was exposed to the cold of a severe frost, and the consequence was that the bomb burst by the congelation of the water. This expansive power of water in freezing is of infinite importance in the preparation of soils by the disintegration of rocks, and the pulverization of the ground after it has been turned up.

2801. *Water assumes the solid form*, not only when it becomes ice, but likewise in many cases where it combines chemically with other bodies; for instance, when salts crystallize from their solutions in water, a certain portion of this fluid becomes fixed, and is called *the water of crystallization:* a familiar example of this may be given in the slacking of lime, where the water becomes united to the lime, and a dry powder, called *slacked lime*, is the result, and which always contains some water in a state of solidity: this kind of union of a substance with water is called by chemists a *hydrate*.

2802. *That all water which has been exposed to the atmosphere contains a portion of air*, which it has absorbed, may be shown by placing this fluid under the receiver of an air-pump and exhausting it; the air will be seen coming out of the water in numerous bubbles. But this air may also be driven out by boiling; for this purpose the water should be boiled for two hours, and if such boiled water be again exposed it will absorb air as before. About 100 cubical inches of spring water afforded two cubical inches of air, which consisted of ten per cent. of carbonic acid, and the rest atmospheric air, that is oxygen and nitrogen; but different springs vary considerably in the quantity of air which they contain.

Rain water contains usually 3·5 per cent. of air, and 1 per cent. of carbonic acid gas. Snow water, when fresh, has no air.

2803. *Water absorbs various gases in different proportions.* Of some of the acid gases it takes up several times its own volume.

2804. *Water is susceptible of compression,* though in a very small degree. It was formerly thought to be absolutely incompressible; and it may be still considered so for all practical purposes; but it was shown long ago by Mr. Canton, and more lately by Mr. Perkins, that it can be compressed in a small degree by applying a very great force: it has been calculated that, by a pressure equal to 2000 atmospheres, it may be diminished $\frac{1}{12}$ part of its bulk, though Œrsted considers this estimate as somewhat too great.

2805. *Water is the most convenient material to serve as a standard for comparing the weights of other substances,* and their weight, compared with an equal bulk of water, is termed their *specific gravity;* therefore, in making tables of the specific gravity of various substances, water stands as 1·000. As water expands with heat, and contracts with cold, the weight of a cubic foot, or any other measure of water, must be somewhat less in warm weather than in cold; and on this account, when it is spoken of as a standard, it is always supposed to be of a certain fixed temperature. By very accurate experiments made lately, in consequence of the act of Parliament to regulate weights and measures, it has been ascertained that a cubic inch of distilled water at the temperature of 62°, barometer 30 inches, weighs 252·458 grains. An imperial pint, at the same temperature and state of the barometer, weighs twenty ounces avoirdupois. Any water heavier than this must contain some other substances, and, consequently, be less *pure.* Water is 816 times heavier than atmospheric air.

2806. *Water is a very powerful solvent;* hence it is very important, both as a natural agent, and in a great number of processes. Substances are remarkably distinguished as they are soluble, or not, in water. Frequent mention of the solubility or insolubility of substances in water will be found throughout this work.

2807. *Water absolutely pure is, perhaps, never found in nature.* It is nearly so in many instances; but in consequence of its being a powerful solvent, it soon becomes contaminated, more or less, by foreign substances. The purest water that can be found in a natural state is obtained by melting snow that has just fallen in a clean vessel at a distance from buildings, or by collecting rain water in very clean vessels at a distance from houses. But the chemist finds that, even then, the water is not absolutely pure; it has received, although in a very minute quantity, some adventitious matter in falling through the atmosphere; and it contains a portion of air, which may be separated by the air-pump. All the varieties of water which are found on the surface of the earth, or rising in the form of springs, are, as we might expect, still more impure, containing various substances which the water has dissolved. It is by art alone that we can obtain the purest water: to procure it we must employ distillation.

2808. *Distilled water is the purest state in which we know this fluid.* When heat is applied, the pure water alone rises in the form of steam, and the salts, and all other substances, dissolved in it, sometimes in very minute quantity, will not rise with the vapour, but remain behind; and thus distillation enables us to free water from any contamination by other matters which it may contain.

The process of distillation effects no change whatever in the water itself; it merely separates the pure fluid from its impurities. Water, when distilled, is quite colourless, beautifully transparent, entirely void of taste and smell, and it is lighter than any other water. It is perfectly soft; soap dissolves in it completely, presenting an opaline appearance.

2809. *Distilled water is absolutely unchangeable.* Time has no effect upon it, if kept ever so long. Notwithstanding its purity, however, it is little used except for medical purposes, or in experiments, partly on account of the trouble of preparing it, and partly because the process of distillation deprives it of the air which water always has in a natural state, and which is essential to its being an agreeable beverage: for want of this air, the taste of distilled water is vapid, although it is stated by some physicians to be an excellent solvent of the food.

In places where no water can be procured but which contains too much salts to be proper for drink, recourse may be had to distillation; but then it will be proper to suffer the distilled water to be exposed to the air for several days before it is used, and to agitate it by pouring it several times from one vessel to another, to facilitate the absorption of common air, and restore its usual taste.

The purest distilled water is obtained from rain water, and when it is required to have it absolutely pure for pharmacy, or very nice experiments, it is usual to employ glass or silver vessels for the distillation. But this nicety is not necessary for ordinary occasions: any tin kettle fitted up as a still will do sufficiently well, and any one at all acquainted with the subject may easily contrive a method of having a constant supply of distilled water sufficiently pure by means of the common kitchen fire. This would be extremely easy in a kitchen where a boiler is attached to a range or grate; for it would only require to have a pipe from the top of the boiler leading to a worm placed in any convenient situation, and passing through a tub or cask of cold water, which must be removed when it gets too warm.

Distilled water is absolutely necessary in the composition of medicines, since impurities which might be of no detriment to water for ordinary purposes might destroy or injure the properties of certain materials in pharmaceutical preparations: hence, in the "Pharmacopœia," apothecaries are requested to use only distilled water. When the water to be distilled contains carbonic acid, if the temperature be low, a small portion of this gas passes over with the steam, and is found in the water when condensed, a circumstance which would be injurious in medicines: for instance, if distilled water were used, as it always ought, for diluting solutions of subacetate of lead, or, as it is called, sugar of lead, a cloudy precipitate would be seen, owing to the formation of carbonate of lead, which would render this preparation less effective as a lotion; but if distilled water, perfectly pure, be employed, no such precipitate occurs. This is the reason why the apothecary throws away the first tenth of the product in distillation; but for the purposes of drink, this very minute portion of carbonic acid would be no detriment whatever. The distillation should not be carried on till all the water in the still be driven off, because, when it is reduced to within about four tenths, a decomposition of the substances left is apt to take place, and a disagreeable taste communicated to the product, which would defeat the desired object.

2810. *Water, in the ordinary state, contains*, besides common air, a small quantity of another gas, the carbonic acid gas, which we also mentioned under "Ventilation," and which we shall again have occasion to speak of under "Fermentation." This gas, which assists in giving a brisk taste to spring water, distillation drives off; and this is likewise restored by exposure for a short time.

Sect. III.—Rain Water.

2811. *Rain water is the next in purity to distilled water*: and it is the purest, and, of course, the softest, of any natural water.

2812. *The origin of rain* is water which is evaporated from the sea and land. By the heat of the sun this liquid rises in vapour, and after ascending to the higher regions of the atmosphere, where constant cold prevails, it is condensed into mist, which appears to us as clouds; these float in the air as long as the temperature remains the same, but when they enter currents of colder wind, or are affected by electricity, they are farther condensed into minute drops of water, which ultimately unite together and descend as rain. One might expect that rain water, falling immediately from the clouds, should be absolutely pure, and entirely free from all other matter. This, however, is not exactly the case. It always contains a certain proportion of common air and of carbonic acid gas, which, however, are useful, and, as we have stated above, are the cause of its agreeable taste. But rain water, even when collected with the utmost care, is said by chemists sometimes also to exhibit traces, though very slight, of muriatic and nitric acids, together with carbonate of ammonia.

A small quantity of carbonic acid being a component of the atmosphere, its absorption by rain is easily conceived; but it is not so easy to account for the existence in it of the other acids. Rain, also, falling through the atmosphere of a smoky town, collects in its descent some impregnation from the impurities in the air above the houses. The quantity, however, of all these deteriorating matters is exceedingly small when it has been properly corrected; they can only be detected by the most delicate chemical tests, and are too insignificant to be regarded in employing rain water for the ordinary purposes of life, when used fresh; yet they are often sufficient to render it liable to spontaneous change when long kept.

From the great purity of rain water, its solvent powers are greater than those of any other natural water; hence it soon becomes impregnated with whatever matter it meets with that is at all soluble in it. In hot climates it is apt to become full of animalculæ, and at last to acquire a strong putrid smell from the decay of the animal and vegetable substances contained in it. If properly collected in this climate, however, it keeps a long time.

2813. *To obtain rain water in a state of complete purity for the purpose of examining it*, it should be collected in wide vessels perfectly clean, placed in some open space as far as possible from the smoke of towns, where they can receive the rain immediately from the clouds without its being suffered to fall upon or touch any other substance. Whatever is collected from ordinary roofs is more or less contaminated with whatever happens to be loose, and there is generally some soot from the smoke of chimneys, and fragments of loose mortar, together with a variety of matters that have been blown there by the wind. These materials, however, are not of such a nature as to make the water hard; and provided the roofs are kept clean, it will be perfectly soft, and, if suffered to settle, and filtered, will be nearly as pure as that which is collected immediately from the atmosphere. In countries or districts where water cannot be had from springs or any other source, large roofs are constructed purposely for collecting it. But the substance of which roofs consist is important to consider in collecting water from them; those which consist of lead, copper, or zinc are altogether improper, as the water would certainly be impregnated with the oxydes of these metals, and rain water in particular is found to exert a solvent power on metallic lead. In tiled roofs, where there is a great deal of mortar, the water from them frequently has some impregnation of lime, not, however, sufficient to deteriorate it to any considerable degree, except while the roof is new: wood is also improper. Slate is quite insoluble in water, and, in that case, there being generally no mortar, the water will receive no impregnation, except what may arise from smoke and dust, or what may be produced by the lead gutters and pipes, if there are any. Dripping eaves, and earthen-ware pipes placed below them, are most to be recommended where it is wished to collect water from roofs; and cisterns or tanks formed of slate, stone, or brick, covered with cement or stucco, are better to keep it than wood; lead is particularly improper. It would be very easy to construct cisterns with filters so contrived that rain water might at all times be drawn from them in a state of great purity; and in this manner almost every house, at least in the country, might be supplied with the very best and purest soft water. It has been calculated that the average quantity of water which falls in a square yard of surface in Britain, in the course of a year, is 126 gallons. If, therefore, there be 100 square yards of roofing, it will give 12,600 gallons, which would be an ample supply for all the purposes of a small family.

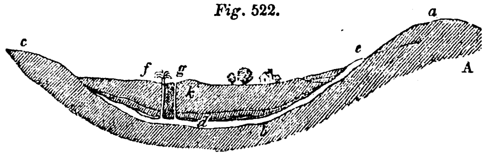
2814. *Rain water, carefully collected and filtered, is extremely agreeable to the palate, and perfectly wholesome.* From its great softness, it is also particularly fitted for the purposes of the laundress. For the mode of preserving it, see Section 10, "Filtration," and Section 12, "Cisterns and Tanks."

Sect. IV.—SPRING WATER.

2815. *The original source of all spring water is rain,* which, falling upon high ground, filters through the soil and the strata of the earth so long as they are porous, until it is stopped by some impervious substance, as rock, or tough clay; it will then find its way along the surface of this bed, until it arrive at some crevice or opening, through which it forces its way out on the surface. From this description of springs, it is obvious that the water which they afford would be equally pure with rain water, provided it does not meet with any substances in its passage through the earth which it can dissolve.

2816. *This will be rendered more clear if we consider the accompanying diagram.* Suppose A to be high ground, perhaps rocky, or, at least, impervious to water, and let *a b c* (*fig.* 522) represent the surface of this *impervious* stratum, having a stratum of sand, or some *pervious* substance, *d*, lying upon it; and over this let another *impervious* bed, *k*, cover the last. The rain which falls on the surface of the high ground at *a* will run down the slope of the hill until it comes to the sandy stratum at *e*, and it will sink down into the sand, and make its way to the lowest part of the sandy stratum. If there should happen to be fissures at *f* and *g* in the upper impervious stratum *k*, the water which entered at *e*, and went down to *d*, will be forced up through these fissures, because *e* is at a higher level; and it will issue out on the surface of the ground at *f* and *g* in the shape of springs. This is the origin of springs in general; they are the openings through which water is forced that has come originally from some higher ground, and made its way through the soft strata as it would through pipes; and very often the sources of springs lie at a very great distance. But if the rain water was ever so pure at first, in passing through various parts beneath the surface of the earth, where a variety of soluble salts occur, it must frequently dissolve some of them in its passage, and issue more or less impregnated; and the kind of salts and quantity of the impregnation must vary in every locality. Accordingly, spring water is never perfectly pure, nor entirely free from substances dissolved in it, though sometimes the quantity of dissolved matter may be very small, and not so much as sensibly to deteriorate its qualities with reference to domestic purposes.

Fig. 522.



2817. *The salts most frequently found in the water of springs* are sulphate of lime and carbonate of lime; but, besides these, there occur occasionally sulphate of magnesia, or Epsom salt, sulphate of soda, or Glauber's salt, muriate of soda, or common salt, now called chloride of sodium. Alum is sometimes found, though much more rarely; and salts of iron are extremely common, besides occasionally other substances.

2818. *The chief practical distinction in water is its being what is called hard and soft,* qualities which are pointed out by its action on soap. In water perfectly soft, soap dissolves without curdling, and washes with a lather; hard water curdles the soap, instead of dissolving it, and will not do for washing. This distinction is practically so important that it is necessary to explain it clearly.

2819. *What is called the hardness of water*, exhibited in its curdling soap, is owing to its containing a small quantity of certain neutral salts in solution, which have been derived from the passage of the water through the earth, for rain water is quite free from them. These salts, as has been stated, vary in their nature and proportions according to the nature of the earth through which the water has passed; but all these salts which have been just enumerated consist of an *acid* united to some other substance. Sulphate of lime consists of sulphuric acid and lime; carbonate of lime, of carbonic acid and lime; sulphate of magnesia, of sulphuric acid and magnesia; sulphate of soda, of sulphuric acid and soda; muriate of soda, of muriatic acid and soda, &c.

2820. *Now the reason why water that contains these salts curdles soap is this:* Soap consists of alkali, and oil or tallow, and it is the alkali which is the effective material in washing; but the acid of the salts dissolved in the water *decomposes the soap* by having a stronger attraction for its alkali than for the substance with which this alkali is already united, and thus the soap is rendered quite useless and ineffective. *But to make this still more plain*, we shall take a particular salt, and examine in detail what effect it actually produced upon the soap. Sulphate of lime is by far the most general cause of the hardness of ordinary spring water, except it be brackish, and then the salt would be muriate of soda. Sulphate of lime, we have said, consists of sulphuric acid and lime; and soap, we have stated, consists of alkali, either soda or potash, and oil or fat; these two, the alkali and fat, unite to form soap, which is soluble in water, although fat, one of its ingredients, is insoluble. Now, when sulphate of lime dissolved in water comes in contact with soap, the sulphuric acid, having a stronger attraction for the alkali of the soap than it has for its own lime, lets go the lime, and seizes upon the alkali; in consequence of which the fat of the soap is set at liberty. The soap is thus evidently separated into its original constituents, fat and alkali, and is, therefore, no longer soap. The soda of the soap joins to the sulphuric acid, and forms sulphate of soda, and the lime and the fat unite as an insoluble compound, appearing like a curd; in consequence of this the peculiar action of the soap is totally prevented. *And to understand this clearly, let us examine what is this peculiar action of soap.*

2821. *The action of soap is detersive*, that is, it destroys grease, which is only another term for oil or fat of some kind; and the following is the manner in which it takes away or discharges grease: the alkali of the soap unites with the grease, and makes more soap, which, being soluble in water, is thus carried off. But it may be asked, if the alkali of the soap be already united to oil or grease, why should it unite to the grease which it is intended to destroy? The fact is, that if there was a sufficient quantity of oil in the soap to *saturate* it *completely*, it would not act in this manner, and would not be detersive; but in the manufacture of soap, care is taken to have a little less oil than would be sufficient for that purpose, and therefore the alkali can still take up a small additional quantity of oil, which is just what happens in its removing grease in washing. Another question will now naturally occur to one who reflects: if the alkali of the soap be the only effective material, *why not use it by itself?* why make it into soap at all? This is done merely for convenience; if the alkali alone was rubbed upon the linen, it would, as every laundress well knows, burn and corrode it, and it would also corrode the skin of the hands: uniting it to fat, therefore, in making it up into soap, is for the purpose of moderating its strength, and enabling it to be applied for a greater length of time to the desired parts, instead of being, as it would be in the state of soda only, soon lost in the water. It follows from this explanation that the strongest soap has the greatest quantity of alkali.

We must observe that water never contains so much sulphate of lime as to be perfectly hard, or to destroy altogether the action of soap; therefore we find water *more or less* hard; and to a certain extent it may do for washing, though badly.

2822. *Carbonate of lime is another substance very commonly dissolved in water*, and which occasions hardness, as well as being otherwise inconvenient and prejudicial. Carbonate of lime is composed of lime united to carbonic acid, which has been described when treating of "Combustion," Book II., Chap. II.

2823. Common carbonate of lime *not being soluble* in water, it is natural that one should inquire how it can be occasionally held in solution in that fluid? That the carbonate of lime in hard water is dissolved is evident, since water of this kind is perfectly transparent, and not cloudy, as if chalk were mixed with it. It is not possible to account for this circumstance, nor to explain distinctly the mode of remedying this defect in water by depriving it of its carbonate of lime, without entering into the following details, which, although a chemical subject, we shall endeavour to render very simple, at the same time recommending every one to cultivate chemistry so far, at least, as to be able to understand explanations of this nature: a task which is far from being difficult, and perfectly within the easy attainment of every person who has had the advantage of a liberal, or even an ordinary education.

2824. Every kind of limestone or carbonate of lime, of which chalk is one, is *insoluble* in pure water; therefore pure water, running over chalk or other limestone rocks, cannot be impregnated with lime. Were not this the case, we should have no water free from this earth, as it is so abundant in nature; nor should we have springs of water issuing so pure as they do frequently from chalk rocks. But springs of natural water are often impregnated with carbonic acid, which they receive in the earth by means not well understood; the fact, however, is certain; and when such water is exposed to the air, but still more when boiled, the acid gas flies off, and leaves the water free. Now, common carbonate of lime, as, for instance, chalk, is, as we observed, united to carbonic acid, but to a certain determinate proportion only of this acid; it cannot take up any more as common carbonate: no chalk or limestone contains more than this fixed quantity; and we have said that in this condition it is not soluble in water. But, if common carbonate of lime should meet with water holding carbonic acid without lime, the lime of the carbonate will then receive an additional quantity of the acid gas, and thus become *doubly carbonated*, or what is called a *bi-carbonate*, or, as some say, a *super-carbonate;* and this *bi-carbonate of lime is soluble in water.*

2825. Upon these facts the explanation of the phenomenon in question depends. In order that water should have carbonate of lime in solution, it must first have been impregnated, by some means or other, with carbonic acid: how that has happened we cannot always say: we know that this gas issues in abundance from the interior of the earth, as in the case of the famous *Grotte del Cane*, and numberless other instances. Water greedily absorbs this gas, and by its means, in the way just mentioned, it is rendered capable of holding abundance of lime in solution. But what will be the natural consequence of exposing such water, now impregnated with lime, to the air, and, still more, of boiling it? We have said that the carbonic acid will be driven off by exposure; that is, *so much* carbonic acid as was sufficient to convert the common carbonate of lime into bi-carbonate of lime, *but no more.* By boiling, therefore, the bi-carbonate is reduced to common carbonate. Now, what must follow? Bi-carbonate of lime is a soluble substance, and the solution of it i water is transparent; but common carbonate is not soluble, that is, water cannot retain it in solution; consequently, the newly-formed carbonate falls down as a cloudy precipitate. Every one knows that if a common carbonate of lime, as powdered chalk, or limestone of any kind reduced to the state of a powder, be mixed with water, they will not dissolve; but, after causing at first the fluid to be turbid, will, after some time, settle to the bottom as a powdery or pasty mass, leaving the water quite free. This is exactly what happens in the case we have mentioned, with this difference, that the precipitated carbonate does not fall down in the state of a loose powder or soft pasty substance, but forms a hard crust; and it is this crust which we call *furr*, and which lines the insides of our tea-kettles. All waters that deposite furr in kettles or boilers must have had in solution *bi-carbonate of lime*, which has been thrown down in the state of *common carbonate*, in consequence of the boiling of the water sending off and dissipating part of the carbonic acid.

2826. *From this explanation, the remedy for water having carbonate of lime in it will be easily understood.* Boil the water for some time, and the carbonate will separate and fall down. Some waters clog the kettles and boilers much faster than others, owing to their having a very large portion of carbonate of lime. It is well known that this is a serious inconvenience in steam boilers; and when tea-kettles become much furred they do not boil water so readily.

The remedy just mentioned, of precipitating the carbonate of lime by boiling, is tedious, and can only be effected on a small scale: another method has been suggested, which answers immediately, and on any scale whatever, rendering the water soft as far as that depends upon freeing it from the carbonate. Add to the water some quicklime, formed into the consistence of cream, with water. Diffuse this through the water to be purified: the quicklime attracts the excess of carbonic acid in the water, and becomes common carbonate of lime, which is insoluble, while, at the same time, the bi-carbonate, previously held in solution, being deprived of its excess of carbonic acid, also becomes common insoluble carbonate, and both fall to the bottom, leaving the water pure. It is to be observed, however, that though this process will effectually render the water soft, if the hardness be owing to carbonate of lime, and that such water will no longer curdle soap, and may be used for washing, yet there will be danger of more lime being used than is necessary for the purpose, and the superabundance will remain in solution in the water, which is then, in some degree, lime-water; indeed, it will scarcely be possible to proportion the lime so as to avoid this. Quicklime, which is caustic, has been employed with this view by laundresses, and the consequence has been that, using too much, the linen has been corroded and injured. Nor would it be advisable to employ this method with water used as a constant beverage; but for many purposes the method may be valuable.

But, though these methods will free the water from carbonate of lime, the sulphate of lime, another source of hardness, must be treated by a different process. The sulphuric acid, not being volatile, cannot be driven off by boiling; but the sulphate of lime must be decomposed by adding some alkali for which the acid of the sulphate has a stronger attraction than for the lime. This may be either soda or potash. The sulphuric acid will seize the alkali and let go the lime; at the same time the sulphuric acid, being now saturated with the added alkali, can no longer act upon that of the soap. This is one of the reasons why soda is found so useful in washing in some of the waters round London, besides its immediate action as a detergent. In these waters there is generally more or less sulphate of lime, which causes a degree of hardness, and this hardness is destroyed by the soda.

This remedy is sufficient if the water be employed only for washing; but, as the addition of soda to sulphate of lime would convert it into sulphate of soda, or Glauber's salt, it would be a matter for consideration with the physician how far a minute portion of this newly-formed salt would be injurious to the constitution in using the water as a beverage. It is very generally stated that hard water is prejudicial if taken long as a beverage. It is apt to cause a sensation of weight, particularly in that weak condition of the stomach which exists in dyspepsia. The water of Paris contains some sulphate of lime, and occasions uncomfortable feelings to strangers who drink of it for the first time.

2827. Sulphate and carbonate of lime being properly insipid substances, they do not impair the taste of the water nor injure its transparency, while the agreeable coolness of water brought up from a considerable depth in the earth renders it frequently very agreeable; but, though a very minute quantity of these salts may not be prejudicial, there is little doubt that waters very hard are unwholesome if used for a length of time. It has been said that they give rise to calculous complaints; but it is not an easy matter to prove this, since, "with the exception of lime, the substances found in hard waters do not enter into the composition of calculi; their operation, therefore, must be rather of a predisposing nature, and is probably exerted upon the organs of digestion, which are well known to be intimately connected with the kidneys."

Late observations, indeed, have given another view of this subject: the formation of calculi appears to be owing to an undue secretion of lithic acid occasioned by indigestion, generally indicated by acidity in the stomach; and it is now said that hard water, containing an impregnation of carbonate of lime, so far from increasing the disease, acts as a remedy by neutralizing the acid in the stomach, and is, in fact, a useful beverage to this class of invalids. In this respect there may be essential difference between an impregnation of sulphate and of carbonate of lime; and it is only the latter which can be advantageous, acting in the same manner as chalk.

Dr. Paris observes that "animals are more sensible of the impurities of water than man. Horses, by an instinctive sagacity, always prefer soft water; and when, by necessity or inattention, they are confined to the use of that which is hard, their coats become rough and ill-conditioned, and they are frequently attacked with the gripes. Pigeons are also known to refuse hard, after they have been accustomed to soft, water. Hard water has also a tendency to produce disease in the spleen of certain animals, especially sheep."

2828. *The proportion of salts varies considerably* in waters that are considered as hard, and we have stated that no natural water is absolutely free from them. But it is not necessary for the ordinary purposes of life that water shall be as pure as when it has been distilled: when water is transparent, colourless, entirely tasteless, and without smell, and will answer for the purpose of washing, it may be considered as pure and good water; but the salts should not be in such quantity as to stimulate the bowels to increased action, nor should the water refuse to unite with soap.

2829. *Brackish spring water* contains common salt, muriate of magnesia, and muriate of lime, all of which exist in sea water; and the springs must owe these either to some communication with the sea, or to the proximity of some bed of rock salt through which the springs pass. *Brine springs* contain so much salt that it is procured from them by boiling and evaporation; several of these occur in Cheshire and Worcestershire.

[Brine springs, or salines, as they have been called, are very numerous in various parts of the United States, especially in the western section of New-York, where, as on the borders of Onondaga Lake, the brine is of such strength that, from some of the wells or springs, thirty to forty gallons will yield a bushel of excellent salt. The manufacture of salt from the springs of Onondaga county employs many thousands of labourers; and, while it is productive to the proprietors, constitutes a fruitful source of revenue to the state, nearly four millions of bushels being annually inspected at these works. As the improvements in the works, though yearly increasing, are not yet perfect, there is still an immense waste of brine, which might be obviated by greater skill in the process, and improved machinery. Experiments are in progress under the patronage of the state, and these objects, it is hoped, will ere long be secured.

Three modes of manufacturing salt are pursued at the Onondaga springs, viz., 1, solar evaporation; 2, evaporation by artificial heat; and, 3, rapid boiling in kettles.]

2830. *What are called petrifying springs* are intimately connected with this subject, and we cannot introduce their explanation in a better place, as it will throw still farther light on what we have been discussing. The vulgar notion of a petrifying water or spring is, that it will convert into stone any substance thrown into it. This is, however, altogether an erroneous idea; there is probably no such water or spring, in this sense of the term. No water in any country, *as far as is known*, has *now* the property of converting wood into stone. Petrified wood is frequently found imbedded in ancient rocks; but the date of such petrifactions is entirely unknown, and is probably of incalculable antiquity. Modern waters said to have a petrifying quality do not convert the substance of wood into stony matter, but only incrust the wood with a deposition of carbonate of lime, precisely analogous to the furr of a tea-kettle; and the piece of wood so incrusted will be found within this incrustation perfectly unchanged. Several springs of this kind are well known in various parts of England, particularly at Matlock in Derbyshire, where many substances, as birds' nests with eggs, branches and leaves of trees, &c., or, in short, any objects thrown into them, are petrified, as it is improperly called. These springs hold carbonate of lime in solution, in the manner we have stated above; and when the water issues from the ground, and is exposed to the atmosphere, the excess of carbonic acid flies off, without boiling, and the bi-carbonate, thus reduced to the state of common carbonate, is precipitated as a crust over any substances at the bottom. Such objects are, therefore, merely *incrusted with carbonate of lime*, and are properly *incrustations, not petrifactions*, the latter term being applied only to the effect of very ancient and unknown operations, by which every particle of the original body has been removed, and stony matter *substituted* in its place. If a piece of really petrified wood, for example, be broken across, no wood will be perceived in the interior; the whole will be mineral matter. Science is yet unable to explain satisfactorily this effect, as well as many others in the natural history of the earth, and the cause has never been seen in operation.

[Petrifying springs are not infrequent in America, and in Western New-York they are numerous, so that specimens of the most delicate parts of vegetables, replaced by carbonate of lime or silica, without any alteration in their form, are found in great variety. And these are not merely incrustations, as in the formation of stalactites, calcareous tufa, or travertin, but are often true petrifactions, in which the conversion of the wood into stone is proven by analysis, not a trace of vegetable matter being discoverable, the petrifactions consisting wholly of lime in the form of carbonate, with minute portions of silica, alumina, and oxyde of iron.]

2831. *Soft spring water* is nearly the same as rain water; it is, indeed, only the latter which has passed through the earth without meeting with any soluble substances to alter its purity: it is very seldom quite so pure as rain water. Some waters of this kind are so pure as to possess even a medicinal celebrity. The waters of Malvern and of St. Winifred's Well in Flintshire are very pure waters, having no mineral impregnation; and it is thought that their salubrity is owing to the great solvent power which water has when in a very pure state. The sweetness of water is a term that merely expresses its purity.

Although hard water is improper for many domestic purposes, yet there are many cases in which the *hardness is no detriment*, and there are several in which *it is even advantageous*. Soft and pure water has, as we have stated, a much greater solvent power than hard; therefore in culinary operations, where the object is to soften the texture of animal or vegetable matter, or to extract from it and present in a liquid form some of its soluble parts, soft water is the most effective, and to be preferred. In brewing, boiling, or stewing meat, making soup, or any extract whatever, soft water is best.

2832. *But if we consider the cooking of vegetables*, we shall find that in some instances hard water is better than soft; and this the cook knows practically at least, by throwing salt into the water, which makes it hard. Soft water without salt has too powerful a dissolving effect upon green vegetables; it makes too tender, destroying that firmness essential to the preservation of their juices, which are thus dissolved and extracted, and the vegetables consequently rendered insipid, at least to English palates. Together with the juices the green colour is extracted, and the vegetables rendered pale, and even yellowish.

2833. *In boiling fish, likewise*, the contrary to boiling meat, it is not required merely to render the fish soft, but to preserve a certain degree of its firmness. Salt is, therefore, put into the water in boiling fish; hence it is evident that, in this case, hard water is at least as good, if not better, than soft.

2834. *It may therefore be laid down as a rule in domestic economy*, that when the object is to dissolve substances, to render them soft, or to extract the virtues of anything, as in soups, broths, stews, &c., then soft water is the best; but when the object is to cook the food by preserving the juices as much as possible in the substances, hard water is preferable. This, it is to be remarked, although correct, is not the prevailing opinion acquired from books on cookery.

2835. *It should be observed that the terms hard and soft, as applied to water, are only relative:* but water which contains as much as five grains in the pint of saline matter is generally regarded as too hard for washing, and many other economical and manufacturing processes.

2836. *The temperature of springs is uniformly the same all the year round;* hence in summer the water is considerably cooler than any other water: that coming to the surface is more easily affected by the change of season.

2837. *Some springs are, however, naturally warm, and some are hot, and even boiling hot.* When they are warmer than ordinary, they are called *thermal springs*. When a spring is warmer than usual, but still below the temperature of the human body, it is said to be *tepid;* a good example of which is the waters at Buxton, which are always at a temperature of 82°; it is perfectly transparent and colourless, and only differs in its temperature from any ordinary spring. When the spring is warmer than the heat of the body, but not so warm but that the hand may be borne in them, they are called *warm springs*, as those of Bath, which are about 116°; above that point, and to the boiling point, they are *hot springs*. Of the latter there are none in Britain. Thermal waters are generally pure, seldom saline; occasionally, however, they are so, as at Carlsbad in Bohemia, where they have the temperature of 165°. In Iceland, there are several large springs which issue from the ground boiling hot, the most remarkable of which is that called the Geyser.

Sect. V.—well water.

2838. *The water of wells*, sometimes called *pump water*, when the wells are of great depth, is derived from springs; therefore it is essentially the same as spring water, and, like that, must vary with every locality, being hard or soft, according to the various impregnations it has received.

2839. *We stated, when treating of the choice of the situation* for a house, the importance of having an abundant supply of good water. Frequently, to procure this, a well is to be dug, and upon the success of this experiment sometimes the decision on the situation depends.

2840. *The probability of finding water in any spot* depends upon the geological structure of the surrounding district; and as this varies in different places, no rules followed by well-diggers in one district will apply to another. The experience of the well-digger is generally limited to a certain district, and he too often thinks that the observations which he has made in one spot will apply to all the world; and this is very apt to mislead.

2841. *The study of geology furnishes the only true guide* in the search after the proper spots to sink wells in; therefore the geological examination of the surrounding country should precede every other step to be taken with respect to sinking for water.

2842. Wells are always sunk till they penetrate some loose stratum which is charged with water, and which is placed between two other strata impenetrable by it.

2843. Wells are of two kinds: 1, common shallow wells, which are often only reservoirs; 2. Artesian wells, or constantly flowing wells depending upon a high source.

Shallow wells often penetrate a thin stratum or two, *a*, *a*, *fig.* 523, and enter another of sand or some porous substance, *b*, *b*, in which water is contained. When this stratum is pierced, water appears, and is called a spring. Should this not communicate with any higher source, the water that drains into the well sunk down to *c* will not rise upward, and therefore it is necessary to sink this well deeper, so as to form a reservoir for the water that runs into it from the stratum *b*. In some cases, the well is a mere tank into which the water may ooze from the gravel on the surface. This is the case with most of the *shallow wells* round London. The water of such wells of no great depth are very apt to be contaminated by the various substances in the soil, as iron, lime, and even putrid matters; the first two would give them inconvenient properties, but the latter would render the water highly prejudicial. Many instances have occurred of disease being produced from bad water, and particularly in cases where churchyards have been suffered to contaminate the sources from which wells have been supplied, a circumstance which does not appear to excite so much alarm as it ought to do in the English metropolis.

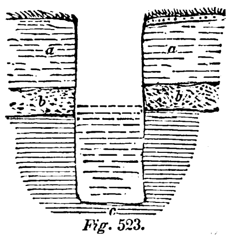


Fig. 523.

2844. *An Artesian well* is a deep well sunk down as at *f*, *fig.* 522, to some stratum fed by a high source. When the stratum with water is arrived at and pierced, the water suddenly rises in the well as high as the source of the spring, *e*, which may even be higher than the ground where the well is sunk, and then the water will pour out as a fountain, or flow over. The *deep wells* in London are of this kind, and the water in them is remarkably pure. The name Artesian is derived from the province of Artois in France, where, it is said, they were first executed. Wells of this kind are now become extremely common, since the operation of boring is often found sufficient.

Sect. VI.—river water.

2845. *River water is composed partly of spring water and partly of rain water.* The principal source of the water of rivers is mist and rain. The former, consisting of the masses of vapour called clouds, are condensed upon mountains, whence a thousand rills of transparent soft water, which unite together into streams and rivulets, either flow into lakes, or, by their union, compose great rivers. Since rivers wind through various regions of the earth, their waters will necessarily vary considerably in the substances which they contain, the nature of which will depend upon the season of the year, and whether they have been increased by snow and floods, or whether, from the heat of the summer, they are more or less impregnated with animal and vegetable matter. Another source of the supply of rivers, but one much less considerable, is derived from springs, which, consisting of water that has long filtered through different strata, is sometimes extremely pure, and in other places highly charged with mineral salts. The proportion of these last, however, being comparatively small, river water is in general remarkably soft, and next in purity to rain water.

2846. *After storms rivers become muddy* from the earthy and boggy matter through which they pass, and which they sweep away as they swell above their ordinary channel. It is evident, also, from what has been said, that the water of rivers must be purer the more we advance towards their sources; and that the greatest quantity of contaminating matter will be found where they nearly reach the sea, the water in their mouths being brackish.

2847. *Some streams that flow over a rocky or pebbly bed,* particularly those in a mountainous country, as in Wales and Switzerland, are remarkably pure and transparent, having been filtered by the clean siliceous pebbles and sand through which they pass; rivers that wind through plains composed of soft strata are often extremely muddy, though they may be free from saline contents.

2848. It is here important to notice and explain the difference between impurities being *mechanically suspended* in water and *being dissolved* in that fluid. If fine sand or clay be agitated in a glass of clean water, a turbid mixture will be produced; but if the water be suffered to rest quietly for a day or two, all the sand and clay will settle to the bottom, and the water will remain perfectly clear as at first. The particles of the sand and clay were merely suspended for a time in the water, in consequence of the motion given to it, their extreme minuteness rendering them easily disturbed; but when that motion has ceased, these particles being specifically heavier than water, that is, fragments of substances that would sink in water, they fall to the bottom, or subside by their superior gravity: rest, therefore, for a certain time, is alone sufficient to separate such substances. But the case is very different with what is actually dissolved in water. Take, as an example, some common salt. This, in dissolving, disappears entirely: it does not cause the water to be muddy, and if the fluid stand quiet ever so long, not a particle will fall to the bottom. The salt is here chemically united to the water, and no rest can have any effect upon it so as to separate it. This is the case with all the salts which are held in water; and, likewise, with some other substances, as mucilage and gelatin, or gum and glue, which will dissolve in the same manner, and will not fall down in consequence of rest.

2849. *Though the water of rivers is produced from the union of that of springs with rain water,* and hence must contain the salts of the former, together with a variety of matters collected by the rivulets and streams which flow over the surface of the earth, yet in general, as we said before, it possesses considerable purity. Much of the carbonate of lime is deposited during its passage through the water, being exposed to the air; and the greater part of the animal and vegetable substances carried down into it is held merely in a state of mechanical suspension, and is not dissolved; for while the water is in constant motion, the putrefaction of these matters does not take place, or in a small degree; hence the greater part may be separated by subsidence when the water is suffered to be at rest, or by filtration.

2850. *But it should be remarked that though river water, even when originally extremely foul, may be purified* by means of filtration to a very considerable degree, yet it can scarcely be expected that it can thus be deprived entirely of all impurities, since, notwithstanding all possible care, some small portion will escape the best filters. If the filters, however, are good, the quantity of these will be extremely small; but the *impurities* which have been dissolved in the water cannot be separated by ordinary filtration. See, farther, Sect. X., "Filtration."

2851. *River water is almost always soft,* because the principal portion of it has been collected from rain water that has never passed through the strata, but flowed only upon the surface, and because the greater part of the earthy salts have had time to be deposited; but from the most noxious impregnations consisting of animal and vegetable matters which have been carried into it, or which have been generated in the rivers themselves, by various aquatic insects and plants, and which have been partly mechanically suspended, and partly dissolved in the water, it is never quite pure. If such river water be suffered to rest, part of this matter will subside, but some will still remain; and though putrefaction did not take place while the water was in motion, yet this effect will happen whenever the water becomes stagnant.

2852. *For this reason it is very desirable that artificial pieces of water* employed to ornament pleasure grounds should, if possible, have some motion, to prevent the bad effects always produced by stagnant water.

What has been said of artificial lakes and ponds applies, likewise, to reservoirs of every kind.

2853. *Rivers which issue from lakes* are generally very pure and transparent, because all the sediment has been deposited in the still water, and the stream that issues is free from the mechanically suspended impurities that were brought into the lake. The Rhone coming out of the Lake of Geneva furnishes a good example of this fact.

2854. *In countries where bogs and peaty marshes abound,* the rivers are often tinged with a brownish colour extracted from the peat, and which does not easily separate from the water.

2855. *The taste of river water* is more vapid, and less agreeable, than that of spring water, because the former has lost all its carbonic acid in consequence of long exposure to the atmosphere; and it is this which renders spring water so pleasant as a beverage.

2856. *Many capital cities are supplied with river water,* as London with the water of the Thames, Paris with that of the Seine.

The Thames water is of itself remarkable for its softness and purity, although in passing through London it receives a great deal of impurities from sewers, and various other local causes. Most of the foulness with which it is in this way contaminated is only suspended, and not dissolved, in the water, and, therefore, mere rest causes much of it to subside, and the greater part of the remainder of what is merely suspended might be separated by filtration: the same may be said of the New River water.

The water of the Seine has been carefully examined by Parmentier, and appears to be of great purity, notwithstanding the numerous manufactories, as dyers, tanners, hatters, &c., which crowd on its banks, but it contains more lime than Thames water.

SECT. VII.—ICE AND SNOW WATER.

2857. *The water from melted ice is nearly pure,* as almost all saline substances are separated by the freezing of the water; even the ice of salt water is nearly fresh, and is used in some places for brewing: but the air contained in the water is likewise separated by this process. Ice water is therefore similar to what has been boiled, in consequence of which fish will not live in it except it be afterward exposed to the air for some time. It has a vapid taste, and does not appear to quench the thirst, nor to act as a solvent in the digestive process so well as rain water. Water from melted snow agrees in its properties with that from ice.

2858. It has been supposed that ice and snow water are unwholesome, and that they give rise to the unseemly disease, the bronchocele, or *goître*, which disfigures so many persons in the Alpine valleys who are obliged to drink snow water for a great part of the year; but this opinion is no longer admitted by physicians, who observe that the "same affection prevails in Sumatra, where ice and snow are never seen; and, on the contrary, that this complaint is unknown in Chili and Thibet, although the rivers of these countries are derived from the melting of the snow with which the mountains are covered." Captain Cook, and other navigators, have proved the wholesomeness of ice and snow water, which they have been obliged to depend upon entirely in high latitudes; and in the polar regions, thawed snow and ice forms the constant drink of the inhabitants during winter, and of the mariners who visit them.

This kind of water is perfectly soft, dissolves soap readily, and will keep good for many years.

SECT. VIII.—SEA WATER.

2859. *The saltness of the sea is, no doubt, one of the wise arrangements of Providence* to prevent the evils which we perceive in stagnant fresh water. The saline impregnation prevents the putrefaction of the animal and vegetable remains with which it abounds.

2860. *According to Dr. Murray's analysis,* a pint of sea water on our coast contains, lime, 2·9 grains; magnesia, 14·8; soda, 96·3; sulphuric acid, 14·4; muriatic acid, 97·7; total, 226·0; or, if we consider these substances as combined in the water, it will be, muriate of soda, or common salt, 159·3 grains; muriate of magnesia, 35·5; muriate of lime, 5·7; sulphate of soda, 25·6; total, 226·0, or 1 of saline contents to about 30 of water. It is the muriates of magnesia and lime that give the bitterness which we taste in water of the sea. This water will not do for washing, on account of the salts which it contains; nor, for the same reason, is it proper for preparing food.

2861. *The steam which rises on the boiling of salt water is* nearly quite fresh, scarcely any of the salt rising with it; hence it might appear that we have an easy method of obtaining fresh water from the sea, since, for this purpose, it is only necessary to subject salt water to the common process of distillation, and the water formed by the condensation of the steam in the usual way will be fresh, the salt remaining behind in the still, or any vessel employed for distilling. Yet simple and obvious as is this process, it does not appear to have occurred to the early navigators, who were often distressed for want of fresh water, when they might have supplied themselves by this method. The ancient Greeks, indeed, who were acquainted with the art of distillation, are said to have procured fresh water at sea by suspending large sponges in the mouths of brazen vessels in which salt water was boiled; when the sponges were saturated, they squeezed out the fresh water. This certainly may be regarded as the infant state of distillation; but the quantity of water procured in this manner must have been very small. The discovery of the process of distilling by the moderns put mankind in possession of a new power.

The first account we have of the obtaining fresh water at sea by distillation is in the reign of Queen Elizabeth, when it was put in practice by Sir R. Hawkins. Experiments were afterward made by Hales, Lister, and various philosophers, and the practicability of the method established. M. de Bougainville, in his voyage round the world, derived great assistance from it; and Dr. Irving received, in 1770, a parliamentary reward of £5000 for introducing it into the British navy. Lord Mulgrave tried it with success in 1773, in his voyage to the North Pole, since which time it has been perfectly understood.

The method practised by Dr. Irving was this: the ship's kettle was divided into two parts by a vertical partition; in one of these divisions was the soup or meat to be cooked, and in the other, sea water to be distilled. The same fire boiled both, and therefore, at the same time that provisions were dressing, fresh water was distilling. Three fourths only of the sea water was distilled off, since, when the brine became strong, the distilled water had a disagreeable taste from a partial decomposition of the brine. The farther distillation was also found to injure the boilers.

This construction has, since that time, been varied in many ways, but the general principle must always be the same. All that is necessary is some method of condensing the steam which is raised by the boiling of salt water, in the manner of a still; and the particular form and construction of the apparatus may be varied to suit the place where it is used. On board ship, advantage is generally taken of the kettles for cooking, and the steam from these is condensed with little expense and trouble. In long voyages, and even where there has been no particular scarcity of water, it has been thought prudent to employ apparatus of various construc tions for this purpose, to lessen the quantity of water taken in, and to provide against accidents.

2862. *But it is to be observed that, although distilled sea water is all but fresh,* and will answer for washing or cooking, yet it is not completely so. It contains a little muriatic acid, and is not very fit for drinking. A little chalk or alkali added neutralizes the acid; still, it is not found so good as to supersede the necessity of having fresh water from the land.

Sect. IX.—stagnant water.

2863. By the term *stagnant* we should understand water simply *in a state of perfect rest,* or altogether without any current, whether it be a lake or a small pond, and whether the water be clean and pure, or very foul. We mention this the more particularly, because many persons mistake the meaning of the term, and suppose that the word stagnant applies only to water that has already been rendered foul by remaining in that condition. Strictly speaking, it is the *state of rest,* and not its quality, that constitutes the stagnation of water.

2864. *But stagnant water exposed to the air, if ever so pure at first, will not long remain so;* for it soon becomes inhabited by myriads of animalculæ, and aquatic insects of a great number of species, many of which pass some of the stages of their lives beneath its surface, and their exuviæ, or remains, become putrefied, and contaminate the fluid. The vegetable kingdom also here extends its influence. There are a great number of plants, many of which, called *conferva,* are so minute as to be scarcely observable by the unassisted eye, which propagate in still water, and often serve as food to the insect tribes.

Thus stagnant water, like every portion of the superficial part of the earth, teems with life; and the accumulation of the dead remains of animals and vegetables communicate to it properties highly deleterious. We stated that water perfectly pure is incapable of change by itself, whether in rest or motion; but no water, however pure at first, if kept perfectly stagnant and exposed to the atmosphere, can continue long in a wholesome state, or fit to be employed in preparing food, from the causes just stated. Boiling and filtration may, indeed, correct much of these bad qualities; still, it can never be so safely used as running water. These observations apply to reservoirs of all kinds when employed in arrangements for supplying water, if freely exposed to the air and light.

2865. *Stagnant water has often a greenish colour,* which is derived from an infinity of minute plants that can only be seen by the microscope: much of this will be retained by the filter, but some will also pass through, as well as part of the mucilaginous juices of plants and animal fluids, and thus the results of putrefaction will probably remain, notwithstanding every care bestowed in filtering; but to what extent it is not easy to say. The transparency alone of filtered water, therefore, will not form a complete test of its purity. See "Filtration," Sect. X.

2866. *The water of lakes and ponds is, properly, stagnant;* but these may vary exceedingly, according to circumstances. Lakes are generally supplied from streams and brooks, which flow into them, some of which have been produced by rain, and others have risen from springs. Here much will depend upon the size of these pieces of water, and the nature of the bottom. The water of deep lakes is agitated by the wind, and is not so liable to have vegetables growing in it. The water of large lakes is generally very pure; but some contain so much salt as to be called salt lakes. It is in shallow water that the numerous confervæ, and other minute species of plants, grow, and which render the water so deleterious; and hence the brownish-green, slimy substances so often seen in shallow ponds.

2867. *The water of marshes is the worst of all.* Marshes are places where the stagnant water is very shallow, and where the greatest quantity of plants of various kinds, and likewise numerous tribes of insects are produced, and, consequently, where their dead remains are the most abundant. The putrefaction of these substances gives rise to poisonous effluvia, which contaminate the air, and often occasion fatal diseases. Such water should be carefully avoided; nor should it be employed in any way whatever for human sustenance if other water can be obtained.

2868. *But the water of a peat bog,* though stagnant, is of a very different quality from that of a marsh. This, indeed, from some property in the peat itself, instead of containing putrid matter, is remarkable for resisting putrefaction; and therefore the same unhealthy gases are not disengaged from the water of a peat bog as from common marshes. This fact is of great importance, and it is observed that the vast peat bogs in Holland, Ireland, North of England, and parts of Scotland, are not at all unhealthy, but the contrary; and the same may be said of those stagnant ponds of water occasioned by the rain filling those cavities from whence peat has been cut. If the swampy surface of bog land in general, and the water contained in these ponds, were equally liable to putrefaction as marshes, the districts containing them would be uninhabitable.

SECT. X.—MINERAL WATERS.

2869. *There are several other salts which occasionally occur in water;* but they are much less frequent than the sulphate and carbonate of lime which we have mentioned. When others occur, they are sometimes in too minute quantity to be perceived by the taste, and can only be discovered by chemical tests. Occasionally, however, they exist in much greater proportion, so as to be discoverable by the palate, and then the water is said to be *mineral*, and is altogether unfit for most domestic purposes. Sulphate of lime and carbonate of lime are generally found together; we rarely have one without the other. *Chlorides of calcium* and of *magnesia* give great bitterness to waters when they occur in them. They are found in the waters of the Dead Sea in Palestine, and in many mineral springs. *Sulphate of magnesia*, or *Epsom salts*, so called because first noticed in the springs at Epsom, where they still exist, is not unfrequent. *Sulphate of alumina* is found sometimes, though rarely.

2870. *When salts of iron are found in water*, it forms what is called a *chalybeate*, and is known by its austere, astringent taste. But the iron sometimes exists in smaller quantity than is sufficient to warrant the appellation of a mineral water. Iron is usually found in water in one or other of two states: either joined to sulphuric acid, constituting sulphate of iron, or what is vulgarly called copperas; or as a bi-carbonate of iron, that is, iron joined to carbonic acid. When the iron is in the state of bi-carbonate, it deposites an ochrey sediment on being exposed to the air for some time, and still more on being boiled; but when it is a sulphate there is no sediment.

2871. *Iron, in whatever mode it exists in water, may be discovered* by its striking a black, or deep violet colour, with tincture of galls, or any substance containing the gallic acid, or tannin (tannic acid); consequently, it would be totally unfit for making tea, as it would convert it into a kind of ink; and it stains black all wearing apparel which have been dyed with tan. Iron is far from being deleterious in small quantity in water, but in a considerable proportion becomes medicinal. The mineral springs at Tunbridge Wells contain bi-carbonate of iron, and that of Sandrock, Isle of Wight, sulphate of iron.

2872. *Chalybeate waters are extremely common:* the most noted in Britain are those of Tunbridge and Cheltenham; but there are several round London, particularly at Hampstead, which were much resorted to formerly.

2873. *Besides the earthy, alkaline, and metallic salts* we have mentioned, mineral springs have considerable quantities of *several gases*. Sometimes there is free carbonic acid gas, and then the water has an acidulous taste. Sulphuretted hydrogen gives it a smell and taste resembling that of rotten eggs, as is the case with the Harrowgate water.

2874. *Accordingly, mineral waters are divided, from their contents*, into acidulous, saline, alkaline, chalybeate, and sulphurous. It would be foreign to our object to go farther into the subject of mineral waters, as they do not come into the list of beverages.

[The mineral springs of the United States are numerous, and found in almost every part of our country, many of which are more valuable as medicinal agents than any in the Old World, as shown by analysis, and, what is still more conclusive, by their curative effects and direct physical action upon the human organism.

The most noted are those of Saratoga and Ballston, in the State of New-York, where, for many miles of surface, there would seem to be a succession of medicated waters gushing forth from the bowels of the earth, inexhaustible in their sources, and each possessing a distinctive, though more or less analogous character in chemical composition and in medicinal effects; and yet some of these springs are found in close proximity to each other, often within a few feet, and yet essentially different both in their nature and effects.

They may all, or nearly all, be said to be chalybeates; but the proportions of the salts of iron they contain vary very remarkably, in some of them being from 5 to 10 grains of the carbonate of iron to a gallon, while others contain less than one fifth of that proportion. The same differences are observed in the relative proportions of other salts, and some of them contain ingredients no trace of which can be discovered in others. Their adaptation to various diseases, and to varied morbid states of the system, requires accurate discrimination, for lack of which there can be little doubt that positive injury has resulted from the indiscriminate, and especially from the excessive use of these waters.

The spring which has the highest reputation at Saratoga is the Congress Spring, and its water is highly carbonated, besides containing a large proportion of chloride of sodium, bi-carbonate of magnesia, and carbonate of lime, with a smaller quantity of the hydriodate and bi-carbonate of soda, carbonate of iron, and a trace of silex and hydrobromate of potash. Its use is found to be decidedly aperient and tonic when freely employed, and in smaller quantities it possesses alterative powers, adapting it to chronic maladies. Congress waters are bottled and sent all over the country, and a regular supply is kept in most of our large cities, so that, as an article of commerce, it is to the proprietor of the spring a source of great emolument. Thousands annually resort thither from every section of the United States during the summer months, either in pursuit of health or pleasure, ample accommodations being provided in the numerous hotels and boarding-houses of the village.

There are also in Virginia a number of valuable mineral springs, little less celebrated for their medicinal virtues, both for drinking and bathing. There are cold, warm, and hot springs, abounding in sulphur, and their curative powers in cutaneous eruptions, and some other chronic diseases, render the several localities of these springs very fashionable resorts. The limits within which these notes are restricted, however, forbid any other detail, although there are various other springs, north and south, which are in great repute among invalids.]

SECT. XI.—PURIFYING WATER.

2875. *As it is sometimes impossible to procure water pure* and fit for domestic purposes, it is important to know by what methods it may be *purified*, as it is called, that is, deprived of those substances which contaminate it; for it is to be remembered that water, in itself, is necessarily pure and incapable of change, and that when it is unfit for use the cause must be attributed to the presence of foreign matters; in other words, substances which do not belong to it.

2876. Before anything can be determined on this subject, it is necessary that we should have a clear idea of the substances with which water is usually contaminated, and of the mode in which they exist in it. We have already explained, when treating of river water, the difference between materials being in mechanical suspension and dissolved in water.

2877. *The bodies which are merely suspended in the water*, and not dissolved, are earthy powders, as clay, lime, and a mixture of various mineral matters of all kinds, which have been washed down from higher grounds, and are completely mixed up in the water, giving it a turbid appearance. Parts of animal and vegetable bodies are likewise found in water in a state of mechanical suspension, as portions of insects, of fish, dead leaves, fragments of wood and branches, grass, and every part of the animal and vegetable kingdoms. We may have a good idea of what may thus be contained in water, by observing what is brought by rivers in freshes, when the water is quite muddy. Extremely fine sand may be in this list of substances; but when the particles are large they subside immediately, and cannot be said to make water turbid.

All the particles that are specifically heavier than water will subside to the bottom; but if any substances should happen to be of the same specific gravity as water, they will not subside, but will remain suspended anywhere in it; and those particles which are only a very little heavier than water will not fall down until after a considerable time. Everything, in short, may be suspended in water that is light enough not to sink to the bottom immediately, and which cannot overcome the agitation of the fluid. But in general all such matters do subside after the water has stood a sufficient time.

It is very remarkable, and a proof how beautiful is the economy of nature, that there are very few substances in the world that are exactly of the same specific gravity as water: were there many such matters, this fluid would scarcely ever be clear.

2878. *Purifying water by subsidence* is performed by collecting it into a reservoir, and suffering it to remain perfectly at rest; when, in the course of time, those substances which are only mechanically suspended will sink to the bottom. But this method alone is very imperfect, and can never effect the complete purification of water, since, as we have stated, there are a number of extremely minute particles so nearly of the same specific gravity with water, that they are not able to overcome the tenacity of the fluid, and therefore remain in a state of suspension, and cause a cloudy appearance. These may be separated by filtration, which we shall next describe. Water may also contain salts of various kinds, which cannot be separated either by subsidence or filtration; for these distillation is necessary, by which the pure water rises in the form of steam, and is condensed again, the salts remaining in the still. The filtration of water being an important subject, we must treat of it at some length.

2879. *Filtration is the most general method of purifying water* for domestic economy. This consists in allowing the water to percolate through a porous material, the pores of which are too minute to allow of the passage of any substance mixed in the water. Straining liquids through a sieve, cloth, or sponge is a coarse kind of filtering; and a great variety of materials are employed to perform this operation, suited to the nature of the liquids and other circumstances. The chemist employs unsized or bibulous paper for his delicate processes, and porous stones have been employed for filtering water for ordinary purposes. Flannel and cloth of various kinds are also used.

2880. *Sponge may be employed for filtering* by compressing it into the neck of some vessel made to hold the water; this substance is very convenient, as it may be easily taken out, cleaned, and replaced.

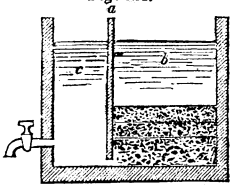
2881. *But the best material for filtering water is charcoal.* This substance not only acts mechanically by its porosity as a strainer, but it has the valuable and peculiar quality of preventing putrefaction by absorbing at once the gaseous matter that is generated, and thus impeding decomposition. Sailors have long been acquainted with this property of charcoal, and they have found it to be an excellent practice to char the inside of the casks in which they take water to sea in long voyages. It was once supposed that the chief use of this was to prevent the water from contracting a disagreeable taste from the wood; but it is now known that it not only effects this, but that it acts much more powerfully by absorbing all putrid matter and offensive odour, and thus rendering, in a considerable degree, even foul and unwholesome water salubrious and transparent.

The best charcoal for this purpose is that produced by burning animal substances, called *animal charcoal*, which is more effective than vegetable charcoal. Charcoal has likewise the property of absorbing colouring matter; brandy may be rendered white by being passed through it, and port wine has been rendered pale; it is also used for whitening the sirup of sugar.

2882. *Nature effects filtration by means of beds of sand.* Water that has percolated through these issues perfectly transparent and clear, and freed from everything except what it holds in solution. Art, imitating nature, employs sand for the same purpose, and filtering beds upon a great scale have been formed for purifying water, the supply of towns, and for domestic purposes. Little more, indeed, seems necessary for rendering water perfectly pure, where the impurities are merely of a mechanical nature.

2883. *To filter water by means of sand,* it is the practice in many places, particularly in France, to construct cisterns in the cellars, and to divide them into two unequal parts by a partition, *a*, *fig.* 524, that does not reach quite to the bottom. The largest of these divisions, *b*, is half filled with layers of sand of different degrees of coarseness, and into this the water to be filtered is put: in passing down through the sand, all the mechanical impurities are detained, and it rises into the other division, *c*, perfectly clear. This method is so simple that it may be practised anywhere without difficulty. The shape and size of the cistern are quite immaterial. If a cock is placed in the smaller division to draw off the water, it should be fixed a little way above the bottom, lest there might be some slight sediment which would be disturbed. It is obvious that the sand can only answer the purpose for a certain time; for it must become clogged with the impurities and sediment from the foul water, and will require renewal more or less often, in proportion to the foulness of the water. The sand should be well washed before it is used, and it should contain no earthy matter, as this would defeat the object of filtration. Clean, sharp sand is best, and it should be separated by sieves into various degrees of coarseness to place in different layers, the finest being put at the bottom.

Fig. 524.



2884. *It may be remarked that when water is filtered by nature through beds of sand,* it *ascends* to the surface, by which the purification is more completely effected than by *descent.* In the latter case, some impurities might be forced through by the weight of the water, or by their own gravity; but, in the former case, gravity must oppose the ascent of the impurities, which are therefore more likely to remain behind. Filters have been executed on this principle, by making the water pass upward through the sand and charcoal, or other filtering materials.

2885. *A very simple apparatus of this kind was made long ago, by M. Parrot,* of Paris, which has been the origin of much of the recent apparatus for this purpose. As it may be very easily executed, it might be sometimes useful to travellers, who may find it difficult, in some situations, to procure pure water. *a b c*, *fig.* 525, represents a curved tube, either round or square, into which sand, or sand and charcoal, are put, up to the level of the dotted line at *c*. A little flannel bag is put into the end *a*, and water poured into this has its coarsest impurities retained by the flannel; and in passing through the sand, in the lower part of the tube, and rising upward to *b*, is completely purified, and drops into a vessel placed below. If found necessary, a piece of linen or muslin may be tied over the mouth, *b*, to prevent any particle of sand coming over. A tube of this kind, about three inches in diameter, will filter about three quarts of water in an hour. The longer the leg *a*, the more rapidly it will filter, from the pressure of the water. The sand should be made pretty compact, for the slower the passage of the water, the more it will be purified.

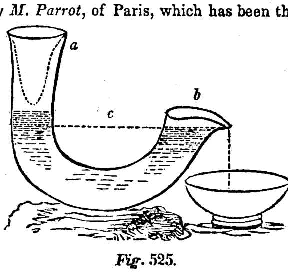


Fig. 525.

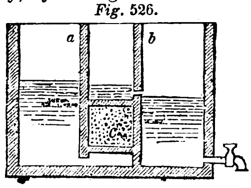
2886. *Upon this principle, an improved mode of filtering has been effected* in cisterns, namely, by forcing the water to ascend through the filter, instead of descending. Here the

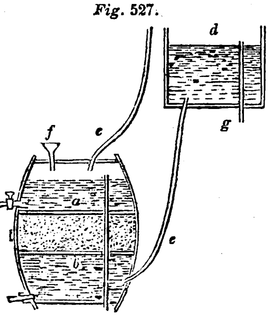
Fig. 526.



cistern has two partitions, *a* and *b*, *fig*. 526. That at *a* does not reach quite to the bottom, and the other has an aperture at *b*. In the middle division a piece of perforated metal, wood, or stone, or a cloth, is fixed a little above the bottom; on this is placed a layer of small pebbles, then coarse sand and layers of charcoal, then finer sand and charcoal, the whole being covered by another cloth, also fixed just below the aperture *b*. The water to be filtered is put into the division *a*; it then passes below the first partition, and by its pressure rises through the perforated plate *c*, and likewise through the pebbles, sand, and charcoal, and passing through the cloth above it, runs through an aperture in the partition *b* into the last division, from which it is drawn by a cock as it is wanted.

2887. *An easy method of cleaning the filtering materials* is by making the water pass through them in a contrary direction to what it does when filtering. For example, supposing, as we have just stated, the division *a* is that which receives the foul water, and *b* that which receives the purified water. Then, to clean the filtering apparatus, reverse the process, and fill the division *b* with unpurified water; it will pass through the aperture in the partition *b*, and descend through the cloth, the sand, and perforated plate *c*, rising in the division *a*, and carrying with it all the impurities, which may be drawn off by a pipe fixed in the bottom.

Fig. 527.



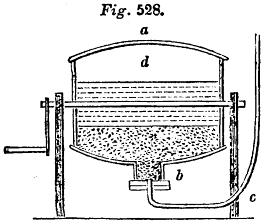
2888. *The principle of filtration being well understood, it may be varied in an infinity of ways*, according to particular localities, or to answer various purposes.

A common cask, *fig* 527, may be divided by partitions, and the filtering materials placed in one of the divisions; or, without any vertical partitions, the cask, as in the annexed cut, may be fitted up for filtering. Let two cross partitions, parallel to the heads, be introduced at *a* and *b*, formed of wood, perforated by a number of holes burned by a hot iron; over each partition put a piece of woollen cloth, and place between them layers of coarse and fine sand and of charcoal. Suppose that *c* is a pipe coming from the roof; the water supplied by it will pass through the filtering materials into the space below *b*, and may be drawn off pure by a cock, or a spigot and faucet at bottom. But suppose that it is desired that the filtration should be performed by ascent, as the most perfect method, then another cistern must be provided and placed on a higher level, as *d*, into which the water to be filtered must be first conducted; the water will descend through the pipe *e*, and enter the lower part of the cask *b*, from whence, by the pressure of the water in *d*, it will force up through the filtering materials into the space above, at *a*, from whence it may be drawn off by a cock. In this case the vertical partition is supposed to be omitted. In either case there should be a waste-pipe in the cask, *h*, to prevent its overflowing, and another in the cistern, *g*.

The foul water may be let off occasionally by the spigot and faucet at bottom. In case of a deficiency of water from the roof, or supposing that none could be had from that source, but plenty from some other source, it is easy to see how the cask might serve as a filtering apparatus. If a funnel, *f*, be put into the top, the water poured into it will pass through the sand in the middle, and come out at the lower cock purified. The best way to clean the sand when it requires it is to take it quite out, wash it and the cask, and replace the sand again.

2889. *Another method of employing a cask as a filtering machine* is the following: hang

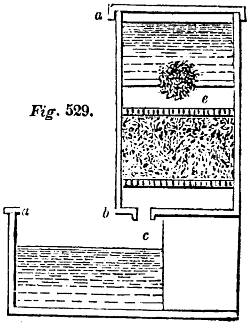
Fig. 528.



the cask, *a*, *fig*. 528, on an axis passed through it, so that it may be turned round by a winch in the manner of a barrel churn: on the lower part fix a short, hollow, cylindrical piece, *b*, to contain a piece of sponge; and connect with it, by means of a flange and screws, a pipe, *c*, to supply water from a cistern placed at some height above. Put sand and charcoal into the cask about one third full. The water will rise through the sponge and sand, and when it arrives at *d* in the cask, it may pass off by a pipe inserted in the end or side of the cask, as may be found most convenient, into any reservoir or vessel to contain it. When it is required to clean the sand, it is only necessary to take off the pipe, *c*, and the sponge, and having stopped up, temporarily, the short, cylindrical hole where it was placed, give the cask, with water in it, several turns round by the winch; this will wash the sand, and make it ready to filter again.

2890. *It must be obvious from the above that a very perfect filtering apparatus may easily be made* by any one possessed of the least ingenuity. All that is wanted is a vessel rather tall than flat, but of any convenient form, as *a b*, *fig.* 529, in which there should be three partitions: the uppermost should have an aperture to contain a sponge stuffed into it, *e*, to stop the worst part of the impurities of the water put in at the top; the two lower partitions may be of wood perforated with small holes by a red hot iron, and having pieces of woollen cloth laid upon them: between these two the sand and charcoal should be put, coarsely powdered; and, lastly, there must be a hole in the bottom vessel, at *c*, through which the filtered water may run into anything placed to receive it; and to avoid the expense of a cock, if the arrangement be as in the wood-cut, where the filtering vessel covers only a small part of the lower one, the filtered water may be got out of it by dipping; and a cover over this part will keep it clean.

Fig. 529.



2891. *It may likewise be seen that any conveniently shaped vessel may serve for a filter*, where sand and charcoal are used: any jar, with a hole in the bottom, or even a large garden pot, may serve as a temporary filter. Put a short bit of tube, or a round bit of wood, with a hole through it, in the aperture in the bottom of the pot, *fig.* 530, so as to project an inch below; then put some sand and charcoal into the pot, and on this pour the water to be filtered. The filtered water may be received in a dish placed beneath. The pot is placed on a stood with a hole.

2892. *Water may be filtered to a certain extent*, even by so simple a contrivance as hanging a thick wick of cotton or worsted thread over the edge of a deep basin or jar, *fig.* 531. The water rises by the capillary attraction of the threads, and continues to run over into a vessel placed below, leaving the impurities behind.

Fig. 530.

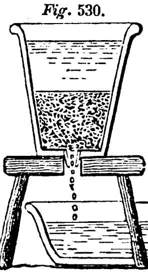


Fig. 531.

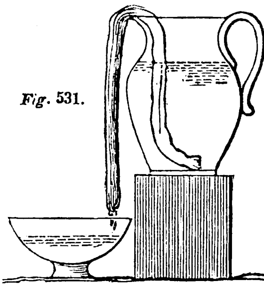

2893. *An excellent filtering apparatus of stone-ware was made and generally sold by John Hawkins, formerly of Titchfield-street, London*, from which most of those now seen in the shops are copied with slight variations. *a*, *fig.* 532, is the vessel into which the foul water is put: it comes through the cock *b*, and drops into the projecting lip of another vessel, *c*, which has a moveable partition pierced with numerous small holes; on this partition is placed a piece of woollen cloth, or a slice of sponge, to stop the greatest quantity of the impurities in the water; after that it passes through the holes into the lower part, which contains charcoal bruised small. This vessel has in the bottom several small holes which permit the water to pass into a third vessel, *d*, from which the filtered water is drawn by a cock. These filters answered the purpose completely, and have the advantage that all the parts could be easily got at, and therefore they were easily kept in order.

Fig. 532.

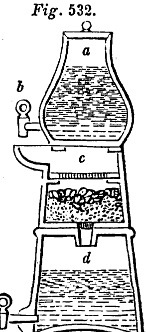

Fig. 533.

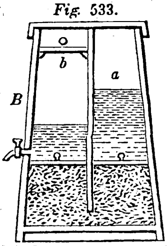
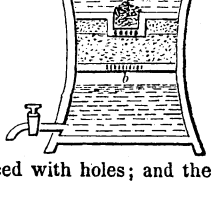


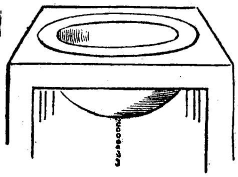
2894. *A large filter, also by Mr. Hawkins*, was made in the following manner: *B*, *fig.* 533, is a cask charred withinside, and having a partition in the middle, *a*, which does not reach quite to the bottom. In the lower part of the cask is put sand and charcoal, or a stratum of charcoal alone, about four inches deep, the upper part of the charcoal in pieces about the size of walnuts, the rest coarsely powdered: this is covered with perforated covers to permit the water to pass through, but to keep the charcoal from mixing with it. The water to be filtered is poured into the division *a*; it then passes downward through the charcoal in the lower part, and rises through the perforated cover in the other division, from which it is drawn off by a cock. The division with the filtered water has an inside cover, *b*, besides the cover over the whole, to prevent any one by mistake pouring foul water into the wrong division.

Fig. 534.



2895. *A*, *fig.* 534, *represents a filtering apparatus made of stone-ware*, which is at present very generally sold in the shops in London: it contains two partitions, which are fixed in with cement. The upper one contains a cavity in the centre pierced with holes; and the lower one is also pierced in a similar manner. Before they are cemented, sand and charcoal are put between the partitions, through which the water put in at the top filters into the lower division, *b*, after first passing through the sponge to detain the coarsest part of the impurities. The filtered water is drawn off by a cock. An inconvenience attends this arrangement, that the charcoal and sand cannot be easily got at to be renewed, on account of the cement; the partitions should be got out when required by the possessor. These filters, though good, have no peculiar superiority over others where the filtering materials are not so concealed.

Fig. 535.



2896. *Water is also filtered by making it pass through a particular kind of porous stones, fig.* 535, *called filtering stones*, which are hollowed out for the purpose in the form of a basin. The fluid percolates through the minute pores of the stones, which are too small to suffer the impurities to pass, and it appears on the outside in clear drops, which are received into a proper vessel. These filtering stones effect the intended purpose, but the filtration proceeds very slowly, drop by drop, and the stones soon clog up, and are then difficult to clean; they should be frequently scrubbed with a hard brush before the mud accumulates too much in them. On first using, water should be passed through for some time before it is drank, as it is necessary to carry off all soluble matter that may happen to be in the stone, and which gives a disagreeable taste to the water. Stones fit for this purpose are found in many parts of the kingdom, particularly in Derbyshire and Durham; but it is said that the best filtering stone comes from the island of Fuenteventura, and the next best from Barbadoes. Both may be procured through Mr. Joseph Bishop, 1 Crescent, Minories, London.

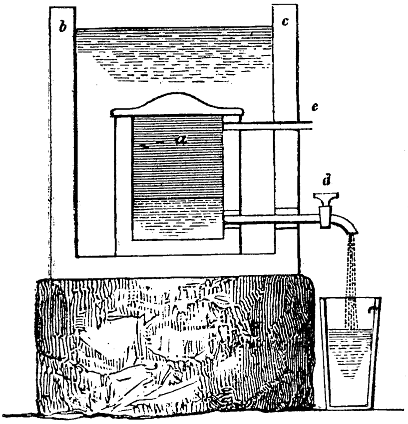


Fig. 536.

2897. *An improved stone filter* is made in the following manner: *a*, *fig.* 536, is a hollow vessel made by hollowing out a filtering stone, with a stone cover cemented on; this is placed in a cistern, *b c*, which may be of stone, slate, or wood. The water to be filtered is put into this cistern, and it passes through the sides of the vessel of porous stone, through the vessel *a*, into the inside, towards which end the pressure of the water arising from its depth assists materially; and this apparatus will therefore filter water more rapidly than the last construction. The filtered water is drawn off by a pipe and cock, *d*, and a small pipe open at both ends, *e*, goes through the cistern and upper part of the filtering stone, for letting out the air as the water comes in, and admitting it as the water is drawn off.

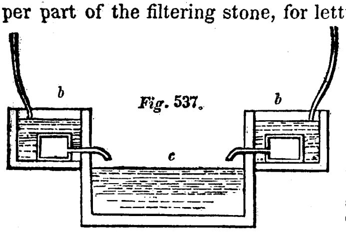

Fig. 537.

2898. *Fig.* 537 represents *an apparatus on a large scale* given in the Gardener's Magazine, vol. iv. Rain water is conducted from the roofs by pipes into the small tanks *b b*, in each of which there is a hollow box of filtering stone, into which the filtered water presses. From these stone boxes the pure water passes by pipes into the great tank, *c*, in the courtyard; this tank is arched over, and from it the water is drawn by a pump.

2899. *Filtering on a large scale* may be easily accomplished by means of several filters which may deliver their filtered water into one reservoir; it is in this manner that the water of the Seine is filtered for the consumption of Paris. The filters made use of there are constructed of vessels containing sand of various degrees of coarseness, and charcoal. A vast number are employed, and pipes or troughs from each of them unite together, and at last empty them into the general reservoir. One great advantage attending this construction is, that every part of the apparatus is accessible, and the filters may be easily renewed when requisite. The performance is very perfect.

2900. Water *contaminated by salts of any kind cannot be easily deprived of them.* Filtration in this case has no effect whatever; and persons who have proposed apparatus for separating salt from water by this process have been totally ignorant of chemical principles, since all salts dissolved in water pass readily through the filters. Neither can any kind of mechanical compression through sand separate the salt from water, as some have erroneously imagined. To render salt or brackish water fresh, other methods must be resorted to; but any chemical re-agents that may be employed to precipitate salts from water must themselves remain in the fluid, and constitute another kind of impurity.

2901. *Distillation is the only effective process by which the water may be obtained quite pure;* but in general this would be too expensive and tedious for ordinary purposes. At sea, where fresh water is absolutely necessary, the distillation of sea water is frequently employed, as we have shown, in order to deprive it of its salt.

2902. It is very important to understand the difference between salts and the soluble parts of animal and vegetable bodies. The former continue in the water without any particular action, and they can be separated by chemical means, or by distillation; but the soluble parts of animals and vegetables decompose and pass into the putrefactive state, giving out gases and other volatile products, which are taken up by the water, and communicate to it highly deleterious properties, some of which are not yet understood, such, for example, as that which generates malaria, giving rise to marsh fever. Such animal and vegetable substances may be in a great measure, or entirely, separated by filtration, if that method be employed before the substances are decomposed or dissolved in the water; but after that there is no method of depriving the water of them completely, with such ease that it can be practised as an affair of domestic economy: we have stated that charcoal effects this purpose partially. Such water as contains much animal or vegetable matter is extremely liable to pass into the putrid state.

2903. *The importance of good water on long sea voyages is obvious;* yet, notwithstanding the great care that is usually taken to select the purest that can be got, it frequently happens that, when long kept, and particularly in wooden casks, it undergoes a kind of putrefaction, and becomes unfit for drinking. The cause of this change depends upon the impurities contained in the water. Water that has been naturally filtered through sand, and which does not contain salts, is generally the fittest for being carried to sea; but frequently, from local circumstances, the water of rivers is employed.

Some rivers that do not take their rise from a rocky soil, and which become considerably charged with foreign matter during a long course, even over a widely cultivated plain, are remarkably free from saline contents, but are often fouled with mud and vegetable and animal exuviæ, which are rather suspended than held in true solution. Such is that of the Thames, which, taken up at London when the tide is down, is soft and good water; and after rest and filtration it holds but a very small portion of anything that could prove noxious. It is excellently fitted for sea store, but, after being some time at sea, it undergoes a remarkable spontaneous change. When a cask is opened that has been kept a month or two, a quantity of inflammable air (carburetted or sulphuretted hydrogen) escapes, and the water is very black and offensive. Upon racking it off, however, into large earthen vessels, and exposing it to the air, it gradually deposites a quantity of slimy mud, becomes as clear as crystal, and remarkably sweet and palatable. This effect is owing to the water having contained originally a good deal of impurities, consisting of animal and vegetable matters, which putrefy and decompose, and, in consequence, give out the gases and offensive smell above mentioned; but as soon as the decomposition of all these substances has been completed, and the fermentation has subsided, the water is pure in consequence of having thus got rid of them. Hard waters which contain sulphate of lime become more offensive than those which contain only carbonate of lime, for the former salt decomposes, and its sulphuric acid gives rise to sulphuretted hydrogen, which has the most disagreeable odour.

2904. It would appear that the soluble vegetable matter of the wooden casks formerly employed in the navy contributed to the putridity of the water; for now that iron tanks are substituted for them, the water may be kept much longer without being offensive. The metal becomes oxydized, and the oxyde of iron thus formed mixes with the water, but by its weight and insolubility it soon falls down; or, should a small portion remain in the water, it can have no injurious effect upon health. It might be supposed that this fermentation of the foul matter in river water might be resorted to in order to purify it for the purposes of domestic economy; but this method would be by far too tedious, and nearly the same effect is produced by filtering through charcoal.

2905. *Alum is sometimes employed in purifying muddy water,* which it does in some measure when there is a small quantity of impure organic matter. If alum be added in the proportion of a few grains to a quart of foul water, with agitation, and then suffered to rest for twenty-four hours, a sediment will fall down, the water will become clear, and may be poured off. Here the alum combines with the impurities, as in the case of dyeing, and occasions them to subside. If any alum should remain dissolved, and not combined in the water, a little carbonate of soda may be added; this will decompose the alum, the soda making, with its sulphuric acid, sulphate of soda, or Glauber's salt, which remains dissolved after the rest has been precipitated. A few drops of a solution of the red sulphate of iron added to a pound of water will produce the same effect.

2906. *A patent was lately taken out by Professor Clarke, of Aberdeen,* for a method of purifying water by adding quicklime to it. But this can only unite with any carbonic acid that may be in water, forming carbonate of lime, which will be precipitated along with any carbonate of lime that may have been in the water; but it can have no effect upon the sulphate of lime in water, which is the chief cause of its hardness.

2907. *In many parts of Hindostan the water is very impure,* being wholly preserved in tanks. In that country, a most valuable plant, *Strychnos potaterum,* or the cleansing nut, is said to have the property of purifying the water. The pulp of the fruit, when ripe, is eaten by the natives, and the seeds are dried and sold in every market for this purpose. If one of the seeds be rubbed hard for a minute or two round the inside of the vessel before the water is put in, the fluid, however foul, will, a short time being allowed for it to settle, be freed from all its impurities, the adventitious matters being settled to the bottom, and the supernatant water left clear and perfectly wholesome. These nuts are constantly carried about by the more provident part of our Indian officers and soldiers in time of war, to enable them to purify their water; they are more convenient than alum, and are, perhaps, more wholesome. It may be mentioned as a curious fact, that the fruit above mentioned, having the property of clearing muddy water, is the only safe species of a large tribe of plants which are virulent poisons.

Sect. XII.—chemical tests for examining water.

2908. We stated, under the head "Building" (Book I.), how essential it is to have a supply of good water; and that, if no well existed on the spot where a house is to be erected, it was desirable to sink one for the purpose. The salubrity of water being a matter of the first importance to health, it is proper that what is obtained from this or any other mode of supply, where its purity may be questionable, should be carefully examined before it be used for the usual purposes of domestic economy.

2909. *When good water is first taken up it is perfectly clear and colourless;* but the ex aminer should not be satisfied with holding up a glassful between his eye and the light; he should also pour some into a deep ale glass, into which he should look downward, when the slightest tinge from extraneous substances will appear.

2910. If the water be discoloured in any manner, it is usually owing to some impurity mechanically suspended in it, and which may be removed by rest and filtration, in the manner already described; but the impurities may likewise be dissolved in the water, in which case they will pass through the filter, which has no power of separating them.

2911. *The existence of various substances dissolved in water* may be discovered by the use of what are called *chemical tests* or *re-agents.* These are substances made and kept for this purpose; by the addition of a small portion of one of these tests the presence of a particular substance in the water may be detected. But although it is extremely easy to detect, in this manner, the substances most usually found dissolved in water, yet the complete examination of this fluid, so as to ascertain all the matters that are contained in it, is a subject that requires a very considerable acquaintance with practical chemistry, the analysis of waters being one of the most difficult and delicate of chemical researches. It would be quite out of place here to attempt an explanation of this subject at any length, and we only propose pointing out the methods of ascertaining the presence of those substances with which spring or well water are most generally contaminated, and which cannot be removed by filtration.

2912. *If the water obtained should be so impregnated with salts* of any kind as to be readily discovered by the taste, it would come under the description of a mineral water, and be altogether unfit for domestic purposes; but if it be transparent, colourless, and free from any peculiar taste, it is probably good: nevertheless, it may be hard, for the hardness would not affect its transparency, nor would this be readily discovered by the palate, except that organ had been much practised in tasting waters. Using the water in washing will determine this point to a certain extent: if it makes a good lather readily with soap, it is soft; if not, it is hard.

2913. *The nature of hard and soft waters* has been detailed at such length when treating of "Spring Water," that it would be a useless repetition to describe it again. We shall here, therefore, content ourselves with giving more particular directions for employing the tests.

2914. *The mere fact of hardness may be ascertained* by a solution of soap in spirits of wine, which is the method usually employed by well-diggers. If this be dropped into distilled water, no alteration will occur; but if the water be hard from an earthy salt, the solution of soap will occasion a white flocculent adhesive precipitate, which is owing to the lime in the water uniting to the fat of the soap, the alkali of the latter having joined the sulphuric acid of the lime. This test, however, only proves there is some neutral salt in the water, but does not point out what that salt is. Most salts, however, except those which are calcareous, are discoverable by the taste, particularly if part of the water be evaporated.

2915. *To determine whether the water contains lime* in any form, the *oxalic acid* should be employed, as the best test for this earth. All waters containing lime are more or less injurious to health, affecting the kidneys if they are drank for any continuance. Some of the springs about London contain a great deal of sulphate of lime, and are unfit for washing, and would be unhealthy to drink. To explain the principle upon which oxalic acid proves the presence of lime, it must be observed that lime has a stronger attraction for the oxalic than it has for any other acid; therefore it will quit whatever acid it may be combined with in a dissolved state, and unite to the oxalic, forming an oxalate of lime, which, being insoluble in water, will fall down as a white precipitate. But, instead of using pure oxalic acid, it is better to employ it as joined to ammonia, or the *oxalate of ammonia.*

2916. *To detect the presence of iron in water,* add to it *tincture of galls;* if there be iron, a black precipitate, like ink, will be perceived; but for this purpose the water must not be boiled, for in that case the carbonic acid would be driven off and the iron would fall down, and would not be affected by the test. *Prussiate of potash* in the same case will give a blue precipitate, like Prussian blue. If this test give the same coloured precipitates after the water has been boiled, then the iron is not in the state of a carbonate, but is most probably a sulphate of iron. If it be required to determine whether the salt be a sulphate, add muriate or nitrate of barytes to some of the water, and if it be a sulphate, but not otherwise, a precipitate will appear.

2917. *Sulphuretted hydrogen is easily known* in water by its disagreeable smell, like that of rotten eggs, or by blackening a silver spoon put into it.

2918. *Carbonic acid in a free state* may be conjectured by the brisk, sparkling appearance of the water, and this being destroyed by boiling; but it is accurately ascertained by the water reddening *litmus paper*, and precipitating barytes water before boiling, but not after it is boiled.

2919. *Vegetable or animal matter may be detected* by adding sulphuric acid and evaporating the water; if such matter be present the water will become blackened.

2920. The above are the substances most usually found in water; others, which are more rare, require considerable knowledge of practical chemistry to apply the tests properly.

2921. *From all this we may perceive the necessity of having a chemical analysis made of water* about which we have any doubt, and which is to be used for any important purpose, as in the case of water from newly-sunk wells. But this, as we have already observed, can only be effected by the skilful practical chemist.

Sect. XIII.—On tanks and cisterns for preserving water.

2922. *In some countries, where springs are scarce, and where it rains only periodically,* great care is bestowed on reservoirs or cisterns erected to preserve water. Anciently there were cisterns all over the country in Palestine; these are frequently referred to in Scripture, and many of large dimensions are still to be seen. As the cities were, for the most part, built upon hills or high ground, and the rains fell in India at two seasons of the year only, in spring and autumn, people were obliged to keep water in cisterns in the country for the use of their cattle, and in cities for the convenience of the inhabitants. Ancient subterranean cisterns are described as still to be seen at Constantinople, the vaults of which are supported by several hundred pillars. In modern times, before the discovery of such excellent cements as we are now possessed of, there was considerable difficulty in building cisterns to hold water; at present, from the perfection of our Roman cement, this has become comparatively easy. Bricks laid in Roman cement, and covered on the inside with a coating of that material, form a wall perfectly tight, and impervious to water.

2923. *The choice of a material for reservoirs* in which water is to be preserved for drink or culinary purposes is extremely important. The material which has long been, and is still, generally employed for common cisterns is lead.

2924. *The deleterious effects of lead* dissolved by various substances and taken into the stomach is well known; but it is necessary to adduce proofs of it in this place. Water absolutely pure has no action on this metal if air be excluded; but, if air be admitted, its action is very sensible. In the atmosphere there is always present a certain proportion of carbonic acid, and most waters likewise contain a minute quantity. The carbonic acid acts upon lead, and converts it into carbonate of lead, which is a poison. A white line may generally be seen at the surface of water preserved long in leaden cisterns, where the metal touches the water, and this is owing to a deposition of carbonate of lead, formed at the expense of the metal. Waters differ much in the power of dissolving lead. Some act upon it with great rapidity, as is evinced by the corrosion of the cisterns and pipes. But the consequence of this is not generally appreciated.

Dr. Lamb, who has paid much attention to this subject, and to whom we are indebted for many valuable facts, states an instance where the proprietor of a well ordered his plumber to make the lead of a pump twice as thick as what is usually employed for such a purpose, in consequence of his observing that it was frequently corroded and required constant repairs, not considering that the lead thus quickly dissolved was poisoning his water.

Nothing is more certain than that lead cisterns and pipes become leaky from the chemical action of the water upon them, and it must be equally obvious that in all such cases the water is contaminated with a portion of active poison. This action of water on lead is increased frequently by the circumstance of vegetable matter, such as leaves, falling into the cistern; this will impart to the water an additional solvent power, which points out the propriety of at least keeping cisterns extremely clean where lead happens to be the material employed.

It may be supposed that the quantity of metal thus dissolved, and still more the portion that is actually taken into the stomach, must be too minute to deserve serious attention, and that its effects cannot be appreciable. But, considering the complicated nature of the human frame, it is neither impossible nor improbable that a very minute portion of a deleterious substance taken with our aliment for a length of time may exercise an injurious influence after a series of years, although this effect may not be perceived in a short period. We find this to be the case in the use of spirituous liquors, and in other destructive habits. From a passage in Vitruvius, an architect of the time of Augustus, we learn that the ancient Romans were acquainted with the deleterious effects of lead; and he condemns the practice of conveying water in leaden pipes, as this metal, he observes, renders the water insalubrious; but it is observed that water has no action on lead pipes if they are kept always full, since thus the air is excluded.

It would appear, therefore, to be a matter of common prudence to avoid, as much as possible, the use of metal so dangerous as lead in forming cisterns and reservoirs; or, at all events, if it is employed for this purpose, care should be taken to clean such cisterns or other vessels frequently, and not to suffer any water to remain long in them without being changed. It has, indeed, been confidently stated by physicians that a dangerous, and even fatal colic has attended persons who have been obliged to use for some time water which has been contaminated by lead from pipes and cisterns; and that, when pipes of wood, earthen-ware, or iron were substituted, the water ceased to produce these dreadful effects. Dr. Paris mentions several cases of this kind.

2925. *A very delicate test for the discovery of lead in water* is sulphate of potash, or sulphate of soda, which, Dr. Thomson informs us, will detect it, even should it not exceed one part in 100,000 parts of water. A drop or two of this test in a glass of water will show the presence of lead by a cloudy precipitate.

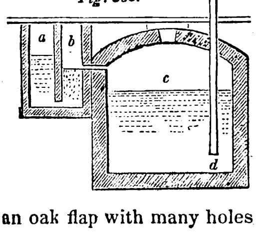
Notwithstanding, however, the opinion which we have just expressed on the impropriety of using lead in general for conveying and preserving water, there is *one case* which forms a remarkable exception to the principles we have stated. It was first shown by Guyton Morveau, and afterward more particularly by Dr. Christison of Edinburgh, that the presence of saline matter of some kinds in water retards the oxydation of lead; and that some salts, even in very minute quantities, prevent it altogether. Such waters, therefore, as have dissolved in them a portion of these salts may be safely conveyed and kept in that metal. Thus a small quantity of muriates and sulphates, which exist in many kinds of spring water, preserve lead from corrosion. "In water containing these," observes Dr. Turner, "the metal gains weight during some weeks, in consequence of its surface gradually acquiring a superficial coating of carbonate, which is slowly decomposed by the saline matter of the solution. The metallic surface being thus covered by an insoluble film composed of the salt and the lead adhering tenaciously, all farther change ceases." The water of Edinburgh has this property; and, likewise, all waters which are hard, though containing sulphate of lime. But no soft water, such as rain water, possesses this advantage.

In recommending that lead cisterns should be frequently cleaned, we must remark that we do not advise that they should be scoured bright; for this would, by exposing the pure metal to the action of the water, occasion it to be more readily dissolved, and destroy the protecting crust; but by cleaning we mean only removing the mud and other loose impurities that may have settled to the bottom, or be attached to the sides, for which brooms and brushes are sufficient.

2926. *In treating of rain water*, we mentioned the possibility of obtaining a sufficient supply by means of a roof properly constructed, a circumstance of great importance in places where wells or springs are scarce.

2927. *Tanks for rain water* have been long employed in some parts of England, particularly in the Isle of Thanet and in Berkshire. They are sunk in the ground, and are of a cylindrical form, resembling a shallow well. The best lining is brick laid in Parker's cement, or very strong mortar, and covered with a coat of cement half an inch thick. It will be best to cause the water to run through a large filter of sand and charcoal previously to passing into the tank. The tank should be arched over with a flat dome of brick, having an opening to clean it out when required, which may be closed by a stone. If the water be first filtered, there will be very little deposite. A pump may be fixed in the tank to raise the water. By means of such a tank almost every house might be supplied with soft and pure water.

Fig. 538.



2928. The annexed wood-cut (*fig.* 538) exhibits a section of the arrangement of this tank with its filter. *a* is the division of the filter into which the rain water is conducted from the roof by a pipe; from this it passes below the partition in the middle, between *a* and *b*, rises through the sand and charcoal in the division *b*, and passes through an aperture into the tank or reservoir, *c*, where it is preserved till raised by a pump, *d*. The top of the tank is arched with brick-work, and has a man-hole to clean it by, covered with an oak flap with many holes bored in it for ventilation.

2929. *Tanks easily and cheaply constructed* have been lately formed at Eastbourne, in Sussex. These have been eminently useful during the last dry summers; they are not liable to decay like wooden vessels, and take up little room.

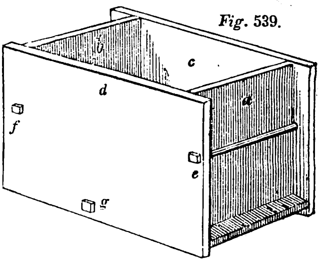
These tanks vary in size; one of less than seven feet wide has served two labourers' families for three years, while most of the springs in the neighbourhood were dry. A tank, twelve by seven feet, has been found sufficient to supply with water a large family and six horses; this was surrounded by only four and a half inch brick-work, and covered in upon the Egyptian plan, by making each row project one third of their length inward before that below it, filling up the back with earth as the building was proceeded with, in order to balance the weight of this overhanging brick-work. At the Eastbourne Workhouse a tank has been made, twenty-three feet deep by eleven wide, of the roughest materials, being only flints of the chalk; and, though they require more mortar than if they had been regularly shaped, only ninety bushels of lime were allowed, including two coats of plaster; and the workmanship is executed like field walls at 10*s*. per 100 square feet, taking care that no clay be used (as worms in time bore through it), and that the Parker's cement be good.

A current of air is said to promote the purity of water in tanks, which is easily effected by the earthen-ware or other pipe which conveys the water from the roof being six or eight inches in diameter, with an opening left in the tank. When the prevailing winds do not blow leaves or soot on the roofs, the water will remain good, even for drinking, without clearing out the tanks above once a year; but in some cases filtering by ascension has been found useful, and effected by the water being delivered by a pipe at the bottom of a cask or other vessel, from which it cannot escape till it has risen through the holes in a board covered with pebbles, sand, or powdered charcoal, as described above.

2930. *The use of such tanks is farther shown* in converting the water that used formerly to injure a public road to the purpose of watering twenty labourers' gardens, by which good crops of potatoes were obtained, when sets not watered failed. Tanks or ponds dug in the chalk four feet deep, what is excavated being added to the sides roofed over, have been found very valuable for the large flocks of sheep in the south downs. Cisterns built with brick and cement, for preserving the rain water from roofs for domestic purposes, are very common in the Ridings of Yorkshire.

2931. *For cisterns on a small scale, for the use of the house, slate is found to be excellent material.* Welsh slate is sawn into thin slabs, and put together with cement, as in the annexed woodcut (*fig.* 539). The ends *a b* are let into groves in the sides *c d*, the latter being held and pressed together by the iron rods with screws and nuts, *e f g*. The bottom is likewise fitted in a groove; thus the whole is kept together in a manner extremely simple.

Fig. 539.



This kind of cistern is very durable, not being liable to get out of repair; and it has the advantage of not in any way affecting the water like lead. A waste-pipe is necessary, of course, as in every other cistern, for this purpose. As slate is liable to be broken by a heavy blow, it may be necessary, in some instances, to provide a wooden casing, or at least a front of wood.

Cisterns of slate may be easily made with a partition, so as to filter all the water that is put into them in the manner already shown.

2932. *The common receptacles for water in small houses* are wooden casks or butts, and these have often been previously used as beer or wine casks. All wood is apt to communicate some unpleasant flavour or odour to the water, except they are charred inside, which they ought to be; and it is too commonly the case that they are left uncovered, and then the water is liable to be contaminated by various substances floating in the air, and by insects of various kinds. They should be frequently cleaned out, and kept carefully covered.

2933. *A ball-cock* is an excellent contrivance, which allows the water to come into a cistern, but shuts of itself when the cistern is full; hence they are always employed in the cisterns supplied by water companies. The plug of this cock is kept in by a screw, or rivet, in the usual manner; it has a copper rod fastened to it, to the other end of which a globular ball of this copper plate is soldered. This ball is so light as to float upon the water of the cistern, and when it hangs down, the cock is open and the water comes in; but, as the water runs into the cistern, it raises the ball and shuts the cock, thus stopping the supply to prevent it from running over. Though this contrivance is very simple, it is sometimes apt to be out of order, and therefore should be frequently examined.

2934. *Every cistern should also have a waste-pipe*, which is a pipe fixed perpendicularly in the bottom of the cistern, having its upper orifice exactly at the level at which it is desired the water should be when the cistern is full. If by any accident the ball-cock should be out of order, or if there is no ball-cock, the superfluous water, that would otherwise overflow, will pass down the waste-pipe.

2935. *Ponds or reservoirs for collecting and preserving water* are frequently necessary for the use of cattle and other purposes in rural and domestic economy, in places where there are no streams or lakes; and these are usually dug out of the ground. It is not difficult to make a pond in a clayey soil, as it is of itself retentive of water; but in cases where the soil is of a loose and porous nature much more care is necessary. It is found, however, that a coat of tough clay, well beaten and rammed in, called *puddling*, is generally sufficient. In some parts of the kingdom, as on the Yorkshire wolds, there is no water for cattle or sheep, except what is collected from rain, and preserved in ponds constructed for this purpose, and they are found to be extremely useful in sheep-walks. The method employed there appears to answer the purpose perfectly, and is as follows: The ponds are made circular, and about forty and fifty feet in diameter, and the excavation is not made above five feet deep in the centre. After the excavation has been cleared out, a layer of clay, well tempered with a little water, is laid over the whole of the bottom, and trodden down and beat with beetles till it forms a compact body of about the thickness of a foot. Upon this a layer of quicklime, of an inch or upward in thickness, is uniformly spread. Over this is put another layer of clay, similar to the last, and trodden down in the same manner. To prevent this clay from being injured by the treading of the cattle, the whole is covered with a layer of coarse gravel or small stones, of such a thickness that the feet of the cattle will not break through it. Some pave the part of the margin by which the cattle enter, which is a good practice, as it is important that the water should be as clean as possible. The use of the layer of lime does not appear to be thoroughly understood; whether it unites with the clay, forming a kind of hard cement, or whether it acts in preventing the worms from boring through the clay, which they are known to do where clay alone is used, and thus let out the water; but it is observed that this mode of construction answers better than where lime is not employed. An improved method of executing this part is to make a mortar by *mixing* the lime with sand, but it adds a little to the expense. Though tough clay is best, yet it does not appear to be absolutely essential; and any earth sufficiently tenacious to bear beating into a solid, compact body, will answer the purpose, though not so well. Paving the whole bottom of the pond will, where the expense and trouble are not an object, be the most complete method.

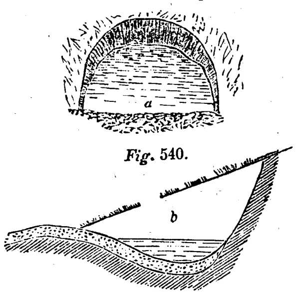


Fig. 540.

2936. *When a pond is to be made upon the slope of a hill*, the form may be a semicircle, as in the ground plan *a*, *fig.* 540, or the segment of a circle. The upper side must be steep, and the lower one of a proper slope for cattle, the bottom being formed out of the materials dug from the hill, as is shown in the section *b*. One pond may be made to supply two or more fields by placing it so that the boundaries of the fields may pass through the pond. Trees should not be planted round ponds or open reservoirs of water, notwithstanding they shade the water from the heat of the sun, and the agreeable effect which they produce, for the leaves which fall into the water, by their decomposition, injure the quality of the water; and such ponds should be frequently raked and kept from aquatic plants, particularly those minute confervæ like green slime, which are very apt to collect in standing water. One great use of paving the whole bottoms of ponds is the facility which this affords of keeping them clean.

2937. *In cases where a pond is supplied by water which runs down sloping ground*, a great deal of impurities is frequently brought along with it, which would render the pond muddy, besides tending to fill it up. It would then be proper to admit the water into another reservoir previous to its entering that from which it is to be used, in order that it may first deposite all its sediment, and the latter will be found extremely useful as manure. The communication may be made by a pipe laid at the surface of the first reservoir, and having its mouth covered with a grating or a plate pierced with holes. As the health of cattle, as well as that of human beings, must depend, in a considerable degree, upon the salubrity of the water which they drink, it would appear proper that more care should be taken to keep the water of ponds in a clean state than is generally bestowed; and a drinking fountain, raised a little from the ground, formed of stone, and kept quite free from weeds, into which the water might flow, filtered from the pond, would not be very difficult to execute upon the principles which have been explained above, and might be a most agreeable object in pasture ground. This latter idea is the more important, since the loose stones with which ponds are covered, as described above, are frequently forced deep into the clay by the feet of the cattle, and the pond is thereby materially injured; besides, sheep are often disgusted when the water is thus rendered muddy, and refuse to drink it.

It is of the greatest consequence that sheep and cattle should be supplied with *pure water*, particularly during the heat of the summer months. For this purpose light, running water is to be preferred where it can be obtained, or, if possible, well water in troughs or shallow tubs, which is very requisite when sheep are confined in folds; but on no account should they be allowed to drink water that has been long stagnant, or in a tainted state, as it must be when it contains any dung. On the Continent the watering of sheep is regarded as a circumstance of the greatest moment. At the best establishments in Sweden and France they are daily watered with running water, or with that obtained from lakes or springs, which is conducted to them by means of pipes into troughs, out of which the animals drink at pleasure, and, consequently, take less water at each time, which is favourable to their health.

2938. In situations where there are natural inequalities of level, it will be easy to construct the pond itself higher than the drinking place, into which it is to be conveyed by a pipe; but where the place is perfectly flat, and the reservoir is to be filled with water collected only from rain, it may be found best, instead of sinking a pond in the earth, to erect extensive low sheds covered by roofs proper for collecting rain water, which might be discharged into the reservoir on the ground; and it has been already shown that any required quantity may be collected by means of roofs. In the best farmeries horses are now more frequently supplied with water, and washed by means of troughs of clean water in the stables, than driven into the pond as formerly.

2939. *The water collected in draining land* may, in some cases, be rendered available for some purposes of domestic economy by conducting it to tanks or other places, where it may first be depurated by deposition, and afterward, if necessary, by filtration. In this case, as much of the drain as possible should be made of drain tiles or earthen-ware pipes. Water so collected has been employed in turning mills and performing other work.

SECT. XIV.—ON PIPES FOR CONVEYING WATER.

2940. *Pipes for the conveyance of water* are made of wood, iron, copper, stone, or pottery.

2941. *Wooden pipes* are the least expensive at first, and are easily made; they are best bored in trees of the proper size, and then the bark being left on preserves them. If small, the passage may be bored by a long auger, turned round by one or two men; but where the pipes are large, and the demand is great, as for supplying towns, machines are employed to bore them. The great objections to wooden pipes are, their want of strength to resist a great pressure of water, and their liability to decay. They are usually made of elm or alder; oak would be preferable, if it were not too expensive. The lengths of pipe are fitted in by enlarging the bore at one end in a conical form with a sort of auger, and cutting the opposite end taper to drive into the conical end of the adjacent pipe, which is hooped to prevent its splitting. Great care should be taken in fitting them well together to prevent leakage, and not to cut away too much of the wood at the taper end, which is frequently the cause of decay. Wooden pipes are apt to generate insects in their decayed and rotten parts, and water lying long in such pipes becomes putrid from the animal and vegetable matter collected in them.

2942. *Cast-iron pipes* are superior to any other for durability and strength. They may be procured of any diameter in lengths of ten feet, and then are united by means of nuts and screws passed through flaunches cast on them; these require to be put together with some cement. After having screwed the pipes together, they first calk the joint with hemp, and then fill it up with a composition of borings or turnings of cast iron, mixed with sulphur and sal-ammoniac, and moistoned with water. The rapid oxydation of the iron unites the whole into one mass, and at the same time expands the bulk of the cement, so as to fill up the space very closely. The use of the hemp is only to prevent the cement from getting into the inside of the pipe. Some have used Roman cement for this purpose; and others have employed melted lead. An idea has sometimes been entertained that the iron is injurious to the salubrity of the water; but a thin black oxyde soon forms upon the inside of the pipe, and defends it from the action of the water, forming a sort of black japan. If the water contains lime, the latter is deposited as a fine crust over the inside, and defends them from corrosion; and there is no fear that iron pipes will fill up with this deposite, since the water only deposites the stony matter from the attraction of the iron, which, being once covered with a slight thickness, the water no longer has access to the iron. Some have put lime into the water purposely at first, when it was found that the water was so corrosive as to become tinged by running through iron pipes newly laid down; a rapid current of lime water being passed through the whole length for a few days, the pipes became coated in the inside with calcareous matter. At first, after this, the water tasted of lime, but it became pure in a short time.

2943. *Stone pipes* have been used; and they are perfectly safe and wholesome, but difficult to execute. Machines have been invented for sawing them out of blocks of stone; but the expense was too great, and they were liable to break.

2944. *Copper pipes* are never employed, except in particular cases, in machinery and apparatus of various kinds.

2945. *Lead pipes* are universally employed for small water pipes, chiefly from the facility of bending them in any direction, and soldering their joints. They were formerly made of sheet lead wrapped round an iron or wooden core, and the joint soldered up. This method was imperfect, as they were apt to give way in the joint; they are now generally made by casting the lead in an iron mould, upon a cylindrical iron rod of the size of the bore of the intended pipe, the lead being three or four times the thickness of the intended pipe, and in short lengths, which are then drawn through holes in pieces of steel in the manner of wire-drawing, till the pipe is reduced to the intended thickness, and drawn out to the proper length. We have already mentioned the bad effects of keeping water long in lead.

2946. *Lead pipes lined with tin* have been made for the conveyance of water where it was in danger of receiving a taint from the corrosion of lead, or for beer.

2947. *Pipes of pottery-ware* are made of a coarse, brown kind of pottery, which is very hard and durable; they can only be made in short lengths, and have one end enlarged to receive the other. To close the joints, tow and pitch are used. These pipes can never be made to bear much pressure, are liable to be broken by accident, and are expensive; but they preserve the water perfectly pure. It appears from some ancient buildings that the Romans sometimes made use of them.

2948. *Pipes are subject to obstructions*, not only from the deposition of sand or mud in the lower parts, where they are curved, but also from air which gets in by accident, and separates from the water, and collects in the upper parts of their bendings. To clear a pipe of this air, if it be of lead, the common method practiced by the plumbers is this: they drive a nail into the place where they suspect the air to be lodged, and while the nail is in, they hammer up the lead round it; they then draw out the nail and suffer the air to escape; when that is all gone, and the water appears, they, with a stroke or two of the hammer, close up the hole in the pipe again, which the lead gathering round the nail enables them to do.

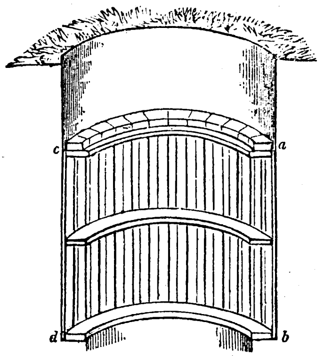
Sect. XV.—Forming Wells and Raising Water.

2949. When water cannot be procured on the surface of the earth, it is necessary to search for it in the interior, where it circulates in numerous places. The origin of well water was shown in Book VIII., Chap. I., Sect. V. Two methods are resorted to for reaching it: digging wells, and boring the earth.

2950. Considerable difficulty is experienced in fixing upon the spot where it is likely that water may be obtained by sinking a well; and much judgment is required, as the operation is very expensive.

2951. *Well-digging* is performed by persons who pursue this avocation exclusively, as it demands peculiar knowledge and practice. The form of wells is always circular. If they should happen to be formed in chalk, no stone or brick lining is necessary; but if made in soft strata, which is most frequently the case, to prevent this from falling in, they are lined within with bricks laid without mortar, which operation is termed *steening*. The steening of a well is a mode of building rather curious, as the internal wall is built and sinks down as the well proceeds. In beginning it, a few feet from the surface a ring or circular curb of wood, called a barrel curb, *a b c d*, *fig.* 541, the size of the well, is laid on the bottom of the digging, and bricks built on it, shown at *c a*, all round, to a considerable height; the well is then proceeded with, and the well-digger cautiously digs away the earth at *d* and *b*, from below the curb, which by degrees sinks down from the weight of the brick-work upon it. When the curb has got to the lowest part of the well that is being formed, the latter is again carried some way farther down, and again the curb and the steening are lowered by the same process as before. This curb is left in the well. If the depth is very great, and the steening will not sink any farther, sometimes they form a new curb within the first, and cause that to sink as they proceed. When they arrive at a spring, it will sometimes burst out with great violence, so as to endanger the safety of the well-diggers, who are then drawn up with all expedition. The depth at which water is found varies in every situation, according to the geological structure of the country. This *latter* branch of knowledge affords the only clew by which the probability of finding water, and at what depth, can be conjectured upon rational grounds; and well-diggers unacquainted with this useful science can prognosticate only from a kind of knowledge and practice of a very limited nature, and are extremely apt to mislead their employers, not always from dishonest motives, but frequently from a total misconception of the true principles upon which they ought to proceed. The thickness of the steening is generally four inches, or half a brick, and the well should be domed over with brick-work, leaving a man-hole twenty inches square, covered with a Yorkshire stone, having a strong iron ring let in in the top to lift it out by. It is usual to contract with the well-digger for a certain depth, that at which water is expected, paying him as extra if the depth should exceed, or deducting if it should fall short of, what is supposed.

Fig. 541.



2952. *Boring the earth to obtain water* has, of late, been practised with great success, not only in this country, but on the Continent, and in many other parts of the world; and it is found to be a very great saving of expense. In consequence, many places are now supplied with this useful fluid where formerly it was entirely wanting. The operation is extremely simple. It consists in fixing an auger or other boring instrument to long iron rods screwed on to each other, which are turned by the action of men with a crossbar. The operation is usually begun by digging a well six or eight feet deep, in the centre of which the boring instrument is placed. The nature of this instrument depends upon that of the stratum to be penetrated, and it is changed accordingly when a stratum of a different degree of hardness is arrived at. Soft clay, or loose, sandy soil, is penetrated by an auger in the form of a hollow cylinder, with a longitudinal slit, *a*, *fig*. 542, or without a slit. This auger is screwed into the rod with a cross-handle turned by the men. If the ground is very hard, a chisel, *b*, is screwed to the rod, and is turned round in the same manner. But, to assist the action of this tool, an elastic pole, *c*, is connected by a chain with the borer, and made fast at one end, while a labourer keeps continually giving to the other end an up-and-down motion, which, corresponding to the beating motion of the men below, helps to diminish their labour. When the ground is thus perforated as far as the chisel and its rod will go, they must be withdrawn, in order to introduce a cylindrical auger, *d*, which has a valve within opening upward; this, passing through the rubbish loosened by the chisel, brings it up as it rises up through the valve, but cannot return. Sometimes an auger like *e* is used, consisting of a hollow cone, having a spiral, cutting edge winding round it. Tools of other forms are likewise employed to suit particular purposes. In order to raise the rod with the auger when required, either to change or to take out the loose matter, a standard is made with three poles over the well, to which a tackle is fixed. The usual length of each rod is about seven feet, and length upon length are screwed together as the boring proceeds. The chisel is generally about four inches wide, and the gouge three inches and a quarter. Raising the rods and displacing them is effected every time the auger has to be withdrawn, which occupies a considerable time. If they meet with rocks, the labour is much increased, as they can get through only by repeated beating the tool up and down to pulverize them. When they arrive at the spring of water which has been expected, the hole is made smooth by passing up and down a rod for this purpose, and a pipe made of tin or other metal is forced down in lengths, which are soldered together as they go down. This keeps the hole open, and prevents the admixture of water from any of the small springs in the side. Upon the whole, the boring is performed with more facility than could be imagined by those who never tried it.

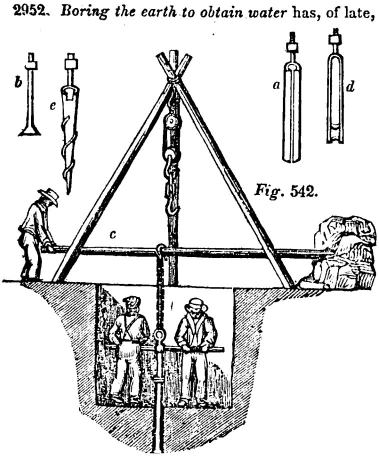


Fig. 542.

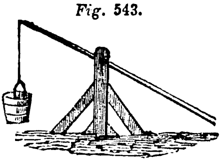
Borings are now made to the depth of several hundred feet, which supply a plentiful stream of water. If the original source from which the water comes be higher than the surface of the ground where the boring is made, the water will overflow; but if the source be at a lower level than the boring, then the water will not rise to the surface of the ground, and it will be necessary to dig a well to the depth to which the spring will rise; and this well serves as a reservoir to contain the water, which must be raised to the surface by a pump.

2953. When a well is formed, it seldom happens that the water rises quite to the surface of the earth, and it is then requisite to have some contrivance by which it is made to reach that level.

A great variety of methods of raising water from wells has been practised at different times and in various countries, each of which may have some convenience or advantage according to the locality and other circumstances.

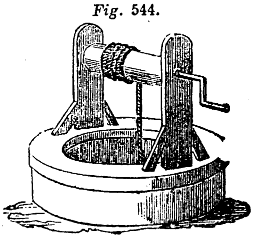
2954. *The lever and bucket* (*fig*. 543) is one of the most simple of these. A long pole, supported by a post, acts as a lever to raise the bucket, and from the end of the lever the water may be raised even by a child by a very trifling exertion. This method is common among the market gardeners near London; but it is only calculated for those cases where the water is very near the surface. It has the advantage of the greatest simplicity, as it can be constructed by any person that can make the lever and upright post.

Fig. 543.



2955. *The next method is the bucket raised by a windlass, fig.* 544. When the well is very deep, or a great supply is wanted, this may be assisted by machinery turned by any of the ordinary powers.

Fig. 544.



2956. But the most convenient method of raising water is by means of *pumps*, which will be described under "Kitchen Furniture," Book XI., Chap. III.

2957. *An old but ingenious mode of raising water* from a well to the upper part of a house is sometimes adopted on the Continent. A post is fixed close to the well; this is connected by a fixed cord with the window or other opening in the upper part of the house where the water is to be introduced. On this cord a wooden collar is placed, and slides freely from one end to the other: the bucket-rope is put through the hole in the collar, and over a pulley in the window, and thus the bucket is raised, first perpendicularly from the water in the well till it comes in contact with the collar, when, the power being continued, the collar slides along the fixed rope, till, together with the bucket, they reach the operator in the window.

2958. It may be proper briefly to notice a few other simple methods of raising water from one level to another, which are occasionally employed.

2959. *Chain of Buckets.*—This consists of a number of buckets fastened to a chain or rope, the two ends of which are united; the chain goes over a wheel, and hangs down into the well, with its buckets having their mouths downward as they descend. On arriving there, the buckets become filled with water, and by the turning of the wheel and the motion of the chain they are brought up, while those on the other side of the chain go down empty.

2960. *The Spanish noira* is a chain of buckets or earthen jars, generally worked by an ass.

2961. *When large buckets are used for deep wells,* they are often made to descend with their mouths upward, and made heavy to sink in the water. They have a valve in the bottom, which rises upward as the bucket sinks, but shuts again when the bucket is raised.

2962. *The Persian wheel* is a large wheel with buckets suspended from the circumference, but so swung that they always hang perpendicularly; of course, one half comes up full, while the other goes down empty.

2963. *The chain pump* is a very simple mode of raising water. It consists of a square or round barrel, placed perpendicularly. A chain is made to pass through this barrel, having on it a great many flat pieces of wood very nearly of the same shape and size as the inside of the barrel The lower end of the barrel being immersed in water, and the wheel turned round, the chain, with its floats or valves, forces up a body of water that fills the barrel. These pumps are found very useful on shipboard, and for draining ponds, and so forth. Sometimes stuffed cushions are used instead of the boards. This pump is often placed in an inclined position.

2964. *The fen wheel,* by which the extensive fens of Holland are drained, is a vertical wheel with floats round the circumference, like a breast wheel for grinding corn. Masonry or wood-work encloses one of the lower quarters of the wheel, so that when it turns round the floats bring up a body of water that fills the trough surrounding the floats. This is also used extensively in the fens of Lincolnshire and Cambridgeshire.

2965. *The bucket wheel* is like an overshot water-wheel, only moved round the reverse way, so that the buckets come up full.

2966. *The endless rope* is a most simple, but not a modern contrivance for raising a small quantity of water. A hair or soft hemp rope is made to pass over a wheel at top, and another at the bottom of a well. The rope is put in motion by a handle, and so much water adheres to it in rising that it is sufficient to make a constant small stream. To prevent the water from descending again with the rope, it is made to pass through a tube at the top to squeeze off the water.

SECT. XVI.—SUPPLY OF WATER TO LONDON.

2967. No city in the world is so well supplied with water as the metropolis of the British empire is at present.

[This may have been correct when this sentence was penned, but not when this work was issued from the London press. The city of New-York, since 1842, by the completion of the stupendous water-works, which for several years have been in progress, has far transcended those of London, both in the purity of the water furnished to the population, as well as in the inexhaustible extent of the supply. The Croton River, 40 miles distant, has been brought, by spacious conduits and aqueducts, to ample reservoirs on the heights adjacent, whence it is conducted through iron pipes throughout the city, and by public hydrants is accessible, without charge, to the entire population. By its descent from the elevated reservoirs, it acquires sufficient head or force to supply public and private fountains, furnishing the citizens, at a trifling expense, with the introduction of it into their upper chambers, for baths and other purposes, while for the extinguishment of fires it is invaluable. The limits which restrict additions to this volume forbid amplification.]

2968. *At the time of the Norman conquest* London was supplied with water from the Thames on the southward side, and on the north of the river by several streams that took their rise on the high ground; the principal of these was the River Fleet, which was once clear and navigable, rising in Hampstead, but which, passing through a populous part of the town, became afterward so filled with impurities as to obtain the name of Fleet Ditch, and is now concealed from view by a vast brick arch, and converted into a common sewer, that conveys its muddy contents into the River Thames. There was another stream, called Wallbrook, that ran through London Wall, through the heart of the city, into the Thames; and a third, named Langbourn, from its great length, which passed through the spot where Fenchurch-street is now placed, and passed by Sherbourne Lane into the river; of these all traces have disappeared, the ground being entirely built upon. Towards the west, a stream called Oldbourne or Holborn, began at Holborn Bars, and ran into the River Fleet. Besides these there were several wells, the names of which remain in several streets, as Clerkenwell, Clement's Well, Holywell, &c.

2969. *Towards the end of the thirteenth century* London had increased so much that the Fleet River became too impure for the supply of water for domestic purposes, and the wells were altogether insufficient. The want of water, one of the first necessaries of life, was severely felt by those who were at a distance from the Thames, and this led to the forming of reservoirs, called conduits, in several places, to which the inhabitants could resort. The first that appears to have been erected was the Great Conduit, in West Cheap, called Cheapside, in 1285, the water to supply which is said to have been brought from Paddington. Many of these conduits were constructed between 1401 and 1610, being chiefly built over wells and springs. One was situated in Lambs Conduit Fields; another near the inn, named after it White Conduit House, and the remains of which existed a few years ago. A regular trade was carried on by persons called water-bearers, employed to convey water from the conduits to the respective houses, and sums of money were frequently left by "good and charitable people" for the purpose of keeping up these conduits; such importance was attached to them that they were put under the care of the lord-mayor and court of aldermen, who annually visited them in great state, to see that they were in proper condition—an occasion which formed a good excuse for a hunting-match and a dinner.

2970. *The conduits having been found insufficient* for the increasing demands, the idea was conceived of conveying water into London by an artificial river; but, although the citizens of London obtained an act of Parliament empowering them to cut and convey a river from any part of Middlesex or Hertfordshire, yet so difficult did such an undertaking appear to be, that it was not carried into effect; nor was a second act obtained in the early part of James I.'s reign more useful in advancing the project.

At length, *Sir Hugh Middleton*, a native of Denbighshire, citizen and goldsmith of London, who had amassed a large fortune by a mine in Cardiganshire, and who had been chiefly instrumental in obtaining the last act of Parliament, offered to the Common Council, on condition of their transferring to him their power under these acts, to undertake the work at his own risk and charge. This being agreed to, he commenced this work in 1609, but experienced numerous unforeseen difficulties through the art of civil engineering being then little understood in England, and from various obstacles through the proprietors of the lands in which the river was to pass. The City of London refused to aid him in his grand and useful design; and his own finances being reduced when he brought the water to Enfield, he would have probably been under the necessity of abandoning the undertaking, had he not petitioned King James himself, who, upon a moiety of the concern being made over to him, agreed to pay half the expense past and to come. The work was, in consequence, completed; and on the 29th of September, 1613, six years after its commencement, the water was let into the great reservoir at Islington.

Notwithstanding the successful accomplishment of this magnificent work, so little was the public sensible of its advantages for some time, that the original shares continued for many years at a small value; but such have been the profits from the project that the shares are now of immense value. To convey the water to various parts of the metropolis was attended with a great additional expense; but, notwithstanding the great benefit thus conferred upon the public, the once wealthy and public-spirited Middleton found himself, at the completion of the whole, a ruined man. Lady Middleton, his widow, received a pension of £20 a year from the Goldsmiths' Company.

2971. *Since that time various companies have been formed for supplying London with water from the Thames;* but complaints having been made of the great quantity of sediment deposited from the Thames water, much attention has of late been given to the subject of obtaining the water in a state of greater purity. No river water is superior to that of the Thames in general; but, when it descends below the bridges, it receives much impurity from the sewers which discharge themselves into it, as well as from manufactories and other sources, which have considerably increased of late. Filtration will, in a great measure, deprive it of its impurities; and, it is well known to those who have examined into this subject, the chemist will find it difficult to distinguish between water taken up at London from that procured higher up at Hampton Court, after each has been so purified.

2972. *A great number of Artesian wells have likewise been* made by boring through the London clay in London, from which a valuable supply is procured of very fine water; and it has been proposed to sink *large shafts* for the purpose of supplying the metropolis; but it does not appear that the quantity that could be raised in this manner would be sufficient, nor that the constancy of supply could be depended upon. Besides, as the water is now managed by the water companies, there seems little cause for complaint; on the contrary, no capital enjoys such abundance of fine water as London.

2973. *Much information respecting the qualities of the Thames and other waters* with which the metropolis is supplied has been obtained, in consequence of the experiments made by Dr. Bostock and other able chemists at the request of the parliamentary commissioners appointed to inquire into the subject. Dr. Bostock confirmed the observation that, when the Thames water was kept some time, a species of fermentation took place, on account of the animal and vegetable matter contained in it; inflammable gas was therefore disengaged, a disagreeable smell was given out, a scum rose to the top, and some impurities settled to the bottom. After some time, the water, by the separation of those matters, became more pure, and free from bad taste and smell, but containing more salts, and therefore harder than at first, which he considers was owing to the salts which had been contained in the organic substances, and which now remained dissolved in the water, in addition to what had been there before. The more foul the water, the more complete will be the depuration, since the fermentation is brought on by the organic matter; and hence we have an explanation of the popular opinion, which we have already mentioned, that the Thames water is peculiarly valuable for sea stores, its extreme impurity inducing the fermentative process, and thus removing from it all those substances which can cause it to undergo any farther alteration. The brown colour which this water often exhibits after its depuration is owing to a portion of what is called extractive matter, derived from decayed vegetable substances, and which is most abundant in the beginning of winter, when the heavy rains bring down much fallen leaves. This colour is not removed by simple boiling, nor by filtration through sand and charcoal; but a little alum or sulphate of iron boiled with the water threw down a precipitate, and left the water colourless. But this extractive, which stains the water, is not in the slightest degree injurious to health, which cannot be said of organic matter in a putrid state.

Much complaint having been made respecting the general quality of the Thames water, to satisfy the public, almost all the water companies not only now filter their water before they deliver it to the houses, but most of them take their supply higher up in the river than where the water can reasonably be complained of. The West Middlesex Company, in particular, take theirs as high up as Twickenham, and, by means of filtration, deliver it in a state of purity quite unexceptionable.

CHAPTER II.

ON FERMENTATION.

SECT. I.—GENERAL OBSERVATIONS.

2974. As several important processes connected with domestic economy cannot be satisfactorily explained, nor clearly understood, without adverting to the principles upon which fermentation depends, we propose in this chapter to give a rather full account of it; and we will endeavour to treat the subject in a familiar manner, so as to be intelligible to those who have little or no previous acquaintance with chemical science. Towards the end, we shall add some observations which, being explained only by chemical principles, may be less easily understood by the popular reader.

2975. *Various beverages, such as wine, beer, spirits*, &c., are the most remarkable products of fermentation; but the ordinary mode of making bread, the production of vinegar, and all the changes which animal and vegetable substances undergo, as well as the manner of checking and preventing those changes, and thus preserving food from decay, also depend upon the principle of this process. From this we may perceive how much the previous explanation of its nature will facilitate the study of several of the most important branches of domestic economy, by enabling us to distinguish the advantages and disadvantages attending particular processes which may have been recommended.

2976. *Animal and vegetable substances alone are capable of fermenting*; for though this term has been sometimes applied to natural changes in mineral bodies, it is incorrect to do so, since these substances are not susceptible of the peculiar chemical actions to which the name of fermentation is now restricted. We shall at present confine ourselves to the fermentation of vegetable substances, the products of which compose a particular class; and we shall treat, in a subsequent part of this work, of the changes incident to animal bodies, by which their decomposition or preservation must be explained.

SECT. II.—FERMENTATION OF VEGETABLE SUBSTANCES.

Although we have already described the chemical constitution of vegetable bodies in Book VII., Chap. VII., where we considered them as food, yet, in order to give a connected view of the subject of fermentation, it will be useful to repeat a few facts which we there stated. All the various kinds of vegetable substances, as fruits, grain, roots, in short, everything produced by the growth of plants, are composed of the same species of materials, but in different proportions; the elementary principles of which they all consist being carbon, hydrogen, oxygen, and nitrogen, but the last only in certain parts of vegetables and in small proportions. We likewise explained that these simple elements are supposed, first, to unite into what are termed the *proximate principles*, as starch, sugar, mucilage, gluten, lignin or woody fibre, and acids, together with various resinous and other matters elaborated by the organs of living plants.

2977. *While vegetables are living*, the elementary principles of which they consist remain united, and such internal motions and changes only go on as are essential to vitality, and the performance of their several functions. The vegetable takes in food from the earth and the atmosphere; this is converted first into sap, from which are afterward elaborated the various secretions, as starch, gum, wood, &c., and the plant grows and increases in bulk by the constant accession of fresh materials.

2978. *But with the life of the vegetable, as with that of the animal, all the functions of nutrition and digestion cease*, and the organic body becomes subject to the laws of chemical attraction. The sap no longer moves through the several vessels; nor is it altered any more into sugar or into starch. The body, whether tree or herbaceous plant, being no longer itself part of the living world, passes into that state in which it becomes fit for the nourishment and support of animated beings. Even then it remains but a short time in the same condition; the minute atoms or particles of which it consists exhibit a strong tendency to separate from each other, and, finally, it is doomed to decompose. The proximate principles, sugar, starch, gluten, &c., are, under the influence of moisture, air, and warmth, resolved into the elements of which they are formed, oxygen, hydrogen, carbon, and, in a few cases, nitrogen, which, absorbing oxygen from the atmosphere, again unite into new compounds, as carbonic acid gas, carburetted hydrogen gas, aqueous vapour, &c. If these changes happen while the dead vegetable continues upon the surface of the ground, the new combinations, being gaseous, are volatilized, disappear, and mingle with the atmosphere; nothing remaining except a small quantity of carbon, which composes a part of the black vegetable mould, together with a minute portion of earths, alkali, and metallic oxydes that were constituents of the plant. It is to this natural decomposition that we apply the terms *decay* and *rotting* of these bodies.

2979. *But previously to this final destruction, or, rather, resolution*, of these substances by natural decomposition, the component parts of vegetables go through several very curious changes, in which they linger, as it were, for a while, before the final separation takes place; and it is to these alterations that we are now about to direct our attention.

2980. *Vegetable substances differ much in their tendency to undergo these changes.* Wood, for instance, which consists chiefly of ligneous fibre, will remain for ages without perishing: the same is the case with resin, camphor, and some others, though mixed with water; oils absorb oxygen from the atmosphere, and alter slowly into resins. On the contrary, starch, sugar, gum, and gluten, or substances containing them, if kept moist, very soon exhibit a disposition to change; a peculiar internal motion takes place, a degree of heat is excited, and the substances are said to *ferment*.

2981. In general, the pure proximate principles of vegetables alter but slowly by themselves. But it is when they are mixed together that the fermentation is most perceptible, and the change most remarkable. Thus, when gluten is added to a solution of sugar and water, the liquid soon runs into vinegar, or into alcohol and vinegar.

2982. The complicated parts of plants, in which the various proximate principles are already mixed by nature, especially the liquid parts, exhibit the finest specimens of fermentation; such as the sap of trees, the juices of fruits, the decoctions of leaves, seeds, &c. It is from such natural and artificial mixtures that we obtain all the products of fermentation which mankind has applied to useful purposes.

2983. *This fermentation, though frequently brought on by art, is, in fact, a natural operation*, and all that we can do is to put substances into the conditions necessary for its action. It is the result of laws established in nature, which we cannot alter in any degree. It is usual to consider fermentation as consisting of successive changes, forming so many *steps* or *stages* in the process, each of these products being extremely different.

2984. *The first stage is called vinous fermentation*, because it is that by which wine is produced; and it might with propriety have been called the *spirituous* or alcoholic stage, because through it alone spirit is formed, not only in wine, but in every other liquor containing spirit. *The second is named the acetous* fermentation, the result being acetic acid or vinegar; and *the last is the putrefactive* fermentation, because putridity is the consequence. These several stages usually follow each other in the order just mentioned. The vinous begins; and this, after a time, passes into the acetous stage, and that into the putrid.

2985. *There are but a few of the proximate principles of vegetables which are capable of undergoing the vinous fermentation: the chief of these are sugar and starch;* and we may perhaps say sugar only; because, when starch assists in the formation of spirit, it is supposed to be first changed into sugar during the process. This fact occasions a very striking distinction in vegetable matters, namely, those which, by possessing sugar or starch, are capable of affording fermented liquors; and those which, being deficient in these materials, cannot be so fermented.

2986. *Some chemists enumerate another species of fermentation*, which sometimes takes place, and precedes all these, viz., the *saccharine* fermentation, by which starch or fecula, and perhaps gum, are converted into sugar. Instances of this may be observed in the ripening or maturation of fruits, in preparing sugar from starch by an artificial process, and in the art of brewing. Still another species of fermentation has been mentioned, the *panary*, supposed to take place in the baking of bread; but this latter is now considered as only the commencement of the vinous fermentation.

SECT. III.—GENERAL PHENOMENA OBSERVED DURING THE FERMENTATION OF VEGETABLES, AND PARTICULARLY DURING THE VINOUS FERMENTATION.

2987. If a saccharine vegetable juice, whether that of the grape or of any other fruit, or the decoction of malt, diluted with a sufficient quantity of water, be left to itself, at a heat equal to the ordinary temperature of summer, that is, from 50° to 70°, it will soon begin to *ferment.*

2988. *The appearances presented by this fermentation will be as follows:* A number of small air bubbles will rise to the surface and break; these will gradually increase in number, until the whole fluid will seem to be in a state of gentle ebullition. An internal motion in the mass will now be evident, and the liquor, though at first clear, will become turbid; the temperature will rise a little; a bubbling noise at length is heard, from the increase of the internal action, and the breaking of the air bubbles on the surface, and the liquor will have a tendency to swell so as to overflow the vessel. The gas or air which is generated, and which ascends in bubbles to the surface, not easily escaping, raises the fluid, and fills the upper part of the vessel; and, if it be examined, it will be found to consist mostly of carbonic acid gas, or fixed air. A lighted candle or taper will be instantly extinguished if held in it; and an attempt to breathe it would produce suffocation. This gas is heavier than common air, and, consequently, though invisible, it will be found to have flowed over the edge of the vessel containing the fermenting liquor, and to cover the floor of the apartment; and as, from its weight, it chiefly occupies only that part of the room, and does not mix readily with the common air, we are not always sensible of its existence, except we make some experiment to ascertain it. A dense froth filled with this gas now covers the surface of the fermenting liquor, and contains a viscid matter, in which it is entangled; the latter is called *yeast,* and has evidently been generated by the process which is going on. At length, after a few days, this action becomes languid; the formation of gas and of yeast lessens gradually; what has been formed of the latter settles to the bottom, and the liquor loses its muddiness, and becomes clear and transparent.

2989. *The liquor which has thus fermented will be found to have been very much altered in its properties:* its sweetness and viscidity have disappeared, and it has acquired a *spirituous* or a *vinous* taste and odour, evidently containing a quantity of *alcohol* or *ardent spirit:* hence this first stage is called the *vinous fermentation.* If the juice of grapes, called *must,* is the fluid that has been fermented, the product or new fluid will be *wine;* if it is a decoction of barley dried and made into malt, the liquor will be *ale;* and if either of these be put into the still, and heat be applied in the usual way, the spirit may be obtained, because, this being the most volatile part, will rise first as vapour in the still. This spirit, when deprived of much of its water by redistilling and other processes, will form *alcohol,* which is only another name for spirit perfectly pure. Pure spirit, or alcohol, whether derived from the distillation of wine, ale, even small beer, or any other fermented liquor, is of the same nature, and indeed absolutely the same liquid.

2990. *The first stage of fermentation always terminates in the production of more or less of the intoxicating fluid, alcohol;* and it is the proportional quantity alone of alcohol or spirit in any liquor which determines what is called its *strength.*

2991. *The explanation of this change* by means of fermentation, in which the sweetness of the liquor has disappeared, and alcohol has been produced, is this: the water remains unaltered, and it is the saccharine matter that has been changed into three new substances—alcohol, water, and carbonic acid. The decomposition has been effected by the chemical power of a certain substance called a *ferment,* a distinct principle from the sugar, and which either exists naturally in the juices of certain fruits, or in the yeast which is added to excite fermentation, as will be particularly described afterward.

It is necessary to observe that no vinous fermentation can occur in any liquid, except it contains a portion of both these principles, *sugar* and *ferment;* and it is only by the mutual action of these on each other that the process can take place.

2992. *But the natural operations by which the sugar is changed into spirit or alcohol, in consequence of fermentation, do not stop when this alteration has been effected;* for this is but the commencement of a series of changes which are to lead finally to its total decomposition, if nothing impedes it.

If the saccharine liquor, rendered vinous or spirituous by fermentation in the manner which has been just described, be exposed to the air in a temperature of about 75°, new changes, after a time, accompanied by a new set of phenomena, will take place. An internal motion will be again perceived; a hissing noise is again heard, occasioned by the disengagement of a little gas; and the temperature rises a few degrees. The liquid again becomes turbid; floating shreds appear on the surface, which partly collect into a sort of cake, and partly subside to the bottom. After this the liquor becomes transparent; but it is found that the spirituous or vinous taste has totally disappeared, and is succeeded by one that is extremely *sour.* In fact, the *acetous fermentation* has succeeded to the vinous, and the alcohol or spirit has been converted into *acetic acid* or *vinegar.*

2993. *If this vinegar be kept, not freed from much water, and for some length of time exposed to the air*, its acidity will gradually lessen, and at last disappear altogether; its surface will become covered with a mould that will increase into a cake, and, instead of the sharp acid taste peculiar to vinegar, the liquid will acquire a very disagreeable odour, and become putrid. This last change, therefore, is called the *putrefactive fermentation.*

2994. *We have stated that these three kinds, or, rather, stages of fermentation generally succeed each other* in the order which has been mentioned, viz., first the vinous, next the acetous, and, lastly, the putrefactive; but, perhaps, instead of considering them as entirely different species of fermentations, it is more correct to view them as the several parts of one great process; at the same time it must be observed that this rule of succession is not invariable. For instance, many vegetables become sour, that is, undergo the acetous fermentation, without any evident appearance of the vinous; and many substances pass apparently at once into the putrefactive stage. But these are cases where scarcely any sugar is present.

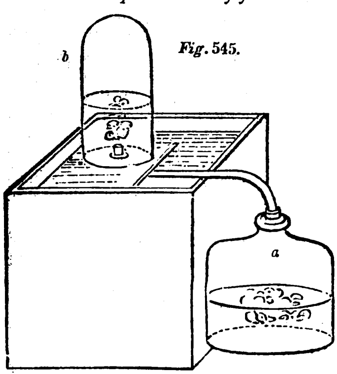
2995. *Certain conditions are necessary, in order that any of these stages of fermentation may take place:* 1, the presence of sugar, or some sort of saccharine matter; 2, a certain quantity of water mixed with the body to be fermented; 3, a natural fermenting principle, or the addition of yeast or some other ferment; 4, a moderate degree of temperature; 5, the presence of air. These several conditions we will proceed to illustrate.

2996. *We stated that sugar is the only substance capable of undergoing the vinous fermentation by which alcohol or spirit is produced.* Every modification of saccharine matter, such as honey, and sweet juices of any kind, can be fermented; and likewise all vegetables, such as carrots, beet-root, &c., that contain sugar; consequently, all substances of this kind will, by fermentation, afford spirit.

But sugar, as stated, will not ferment except it be dissolved in as much water as will make a thin liquid; and it is necessary that there should be much more water than is sufficient to form it into a strong sirup.

2997. *The phenomena of fermentation may be very conveniently examined and studied* by fermenting sugar. Place five parts of sugar with about twenty of water in a glass vessel, *a*, *fig.* 545, furnished with a bent tube, the extremity of which opens under an inverted jar, *b*, full of water; and, after adding a little yeast to the sugar, expose the mixture to a temperature of about 60° or 70°. In a short time bubbles of gas begin to collect in the vicinity of the yeast, and the liquid is soon put into a brisk motion in consequence of the formation and disengagement of a large quantity of gaseous matter, which, passing into the vessel *b*, will be found, on examination, to be carbonic acid gas; the solution in *a* becomes turbid, its temperature rises, and froth collects upon the surface. After continuing the fermentation a few days, the evolution of gas begins to abate, and at length ceases altogether; the impurities gradually subside, and leave the liquor clear and transparent. The only appreciable changes which are found to have occurred during this process are, the disappearance of sugar and the formation of spirit, which remains in the flask, and of carbonic acid gas, which is collected in the glass vessel inverted over water. When the weight of the spirit produced and that of the carbonic acid gas are both added together, they are found to be very nearly equal to that of the sugar; hence it appears that the latter is converted into alcohol and carbonic acid gas.

Fig. 545.



Bodies in a complete state of dryness cannot undergo any kind of fermentation. Though animal and vegetable substances, containing their natural juices, soon ferment, and, at last, putrefy, yet, if the moisture be entirely expelled by drying, they may be preserved for any length of time without change. This will be farther illustrated in Book X., "On the Preservation of Food."

2998. *We stated that the substance called the Ferment is a necessary and important ingredient in fermentation.* The researches of chemists have, perhaps, not yet satisfactorily shown what is the vegetable principle in which this property consists. It is generally supposed to be gluten; some, with less probability, have supposed it to be vegetable albumen; and, if not identical with one of these, it is evidently something very analogous. However this may be, it appears to be essentially necessary, as well as the saccharine principle, to the process, and both together frequently exist in vegetable juices. When that is the case, the juice will ferment *of itself*, if exposed to the proper degree of heat. The *must*, or expressed juice of grapes, is of this kind; to make it ferment nothing is necessary farther than to place it in the proper temperature, as it contains naturally both saccharine matter and the proper ferment. Though we nave stated that sugar is the only substance that can afford alcohol by fermentation, yet it appears that *sugar perfectly pure* will not ferment by itself, and that the addition of some portion of ferment is essential. It is true that solutions of coarse sugars and sirups will ferment of themselves in warm weather, as the sugar refiners often experience to their great inconvenience; but these impure sugars contain a small portion of natural ferment in the other vegetable principles which exist in the raw sugar as imported; and our observation applies only to sugar perfectly pure, when refined. If a solution of fine crystallized sugar be suffered to repose and evaporate, it deposites crystals instead of fermenting; if it has been perfectly fine, the remaining sirup will not ferment; but if it has been imperfectly refined, the residuum contains some of the natural ferment, and it will run into fermentation.

2999. *All vegetable juices containing saccharine matter have also a certain portion of this natural ferment*, as well as the juice of grapes, the sugar-cane, and also the decoction of barley or of malt, and therefore they also will ferment of themselves; but most of these have so little of this principle that the vinous fermentation would take place very slowly, and often so slowly that the acetous fermentation would set in almost as soon, and vinegar, instead of alcohol, be the result; or it might even be the case that the putrefactive fermentation alone would appear.

3000. *It is the practice, therefore, to add an artificial ferment* to most materials, in order to bring on the process of fermentation more rapidly and effectually. In our description of the general phenomena which appear during the process, we mentioned a froth thrown up, called *yeast*, which is generated partly by the very process itself, though the elements composing it must have existed in the mixture; this has the peculiar property of acting as *artificial ferment*, that is, if added to any liquids containing the other necessary ingredient, saccharine matter, it will excite in it the vinous fermentation. Instead, therefore, of suffering the materials for the production of spirit to ferment of themselves, it is the practice sometimes to add to them a portion of the yeast which was produced by a former fermentation of similar substances. Thus, in the fermentation of wort, or the decoction of malt, in the brewing of ale, some yeast from a former brewing is added, not because the wort would not ferment at all without it, but because, in that case, the vinous fermentation would come on very slowly and imperfectly, and the liquor would soon turn sour.

3001. *There appears to be something peculiar in the ferment generated in each stage of the fermentative process:* thus, to produce the vinous fermentation, the yeast thrown up by another vinous fermentation is necessary. The matter deposited in the making of vinegar by the acetous fermentation is capable of acting as an acetous ferment; and it is well known that the putrefaction of flesh is hastened by being placed in the proximity of flesh already putrid. The acetous and putrefactive ferment, however, cannot, like yeast, or the vinous ferment, be procured in a separate form.

3002. *The nature of yeast is a subject of particular interest;* but, although it has been much studied by chemists, it is still imperfectly understood.

3003. *The yeast of beer, analyzed by Westrumb*, was found to contain, in 15,360 parts,

	Parts.		Parts.
Potash	13	Mucilage	240
Carbonic acid	15	Saccharine matter	315
Acetic acid	10	Gluten	480
Malic acid	45	Water	13,595
Lime	69		
Alchol	240		15,142
Extractive	120		

But it is obvious that all these ingredients in yeast are not essential to it as a ferment. From the experiments of the same chemist, it appears that, when the yeast is filtered, a matter remains upon the filter which possesses most of the properties of gluten; and that, when this substance is separated, the yeast loses its properties of exciting fermentation, but recovers it again when the gluten is added. The same thing happens when yeast is kept for some time: a white substance, not unlike curd, separates and swims upon the surface; if this be removed the remainder of the yeast cannot excite fermentation. This substance possesses many of the properties of gluten, though it differs in others; and it is generally considered to be that part of the yeast which is the active or real ferment. This apparently *pure yeast* has been analyzed, and it is found to consist of carbon, water, oil, ammonia, and carbonic acid.

3004. *An experiment of Kirchoff throws considerable light on the nature of yeast.* If pure starch be infused in hot water it is not converted into sugar; neither does gluten become saccharine matter when treated in the same way. But if a mixture of pure pulverized wheat gluten and potato starch be infused in hot water, the starch is converted into sugar. During the process an acid is evolved. The gluten is little altered in appearance, and if the liquid be filtered, most of it remains upon the filter. But it cannot be successfully employed a second time to convert starch into sugar. It appears, therefore, that it is some substance connected with gluten that acts on the starch and occasions this conversion.

3005. *Yeast, then, would appear, as we have said, to consist principally of a substance very similar in composition, and in many of its sensible properties, to gluten*, and when new or fresh it is inflated and rendered frothy by a large quantity of carbonic acid. When mixed with wort this substance acts upon the saccharine matter; the temperature rises, carbonic acid is disengaged, and the result is *ale*, which always contains a considerable proportion of alcohol or spirit. The quantity of yeast employed in brewing ale being small, the saccharine matter is but imperfectly decomposed; hence a considerable portion of it remains in the liquor, and gives it that viscid quality and body for which it is remarkable.

3006. *Yeast may be preserved by drying.* In large distilleries, where the required quantities of yeast are not easily obtained, it has been the custom to procure this substance from a distance; and in order to diminish the expense of carriage, the recent yeast has been put into bags to drain, and afterward has been compressed into solid cakes; or yeast may be preserved by dipping twigs in it and drying them in the air. This dried yeast is found, on trial, to excite fermentation in wort, but not so regularly as recent yeast; and a much larger quantity of the former than of the latter is required. Though dried yeast has been transported to certain distances, particularly in Germany, it has been found impracticable to convey it always in an effective state to India. In a warm, moist atmosphere yeast gradually putrefies, a sufficient proof that nitrogen forms one of its elements.

3007. *The fermenting property of yeast is weakened* by boiling for ten minutes, and is entirely destroyed by continuing the boiling. Alcohol poured upon it likewise renders it inert, on which account its power lessens as the alcohol is formed during fermentation. A thousandth part of sulphuric or acetic acid destroys its peculiar properties: a very small portion of sulphurous acid, or a sulphite, produces the same effect; so, likewise, do mustard, horseradish, and garlic. These substances are, accordingly, sometimes employed to check a too rapid fermentation.

3008. *When the juice of grapes is suffered to ferment by means of the natural ferment which it possesses, without the addition of yeast*, the saccharine matter of the fruit is decomposed during the process; a portion of this ferment is separated, and rises to the top in the form of yeast, while another portion falls to the bottom of the vessel, and is called *lees*. Both of these are chiefly decomposed ferment, which has already acted upon the sugar; but they still contain a quantity of the active and undecomposed fermenting principle, or leaven, and, consequently, can be employed as such in exciting fermentation.

3009. *What the natural ferment of grape juice consists of is not exactly known;* but from an observation by Gay Lussac it appears to require the addition of oxygen before it becomes active; for he observes that, if *must*, or *grape juice*, be heated to 212° in bottles, and corked immediately and carefully, it may be preserved without change, and be conveyed to any distance; but if it be exposed to the air only for a few seconds, it absorbs oxygen, and fermentation takes place.

3010. *Fermentation, once induced, will go on* of itself, if the temperature is sufficient, until one of the principles necessary—either the saccharine principle or the ferment—is exhausted: it will then stop; but it is a curious fact that the very process of fermentation itself occasions the production of a fresh quantity of ferment. If this generated ferment be separated, the process will not proceed so long as if it be continually mixed up with the fermenting fluid: hence the practice of breaking the head of yeast, and stirring it up with the mass, when it is required to prolong or renew the languid fermentation.

3011. *The fermented juice of the grape, and that of wort, or the decoction of malt, are essentially different*, although each contains saccharine matter and a natural ferment. The former will produce *wine*, the latter *beer;* but for the production of the liquor properly called *wine*, another principle besides sugar and a ferment is necessary. This additional principle is *tartaric acid*, which is always present in the juice of fruits, but most abundantly in that of grapes.

3012. *Sugar and tartar alone will not ferment;* therefore tartar cannot be the natural ferment, but the latter is contained in some other principle in grape juice, and probably not very different from the ferment in wort. If the experiment of fermenting sugar and tartar be made in a wooden vessel, they will ferment alone; but this experiment will be deceptive, for the wood supplies the ferment.

3013. *It is essential, also, to a complete fermentation, that there should be a just proportion between the saccharine matter and the ferment, or yeast.* If the yeast be in too great a quantity, there is a danger of the fermentation being too rapid, and that the liquor, after all the sugar is exhausted, should, by a continuance of the fermentation, pass into the acetous state: if, on the contrary, the yeast be too little, the fermentation will be too languid, too little alcohol will be produced, the whole of the saccharine matter will not be decomposed, and the liquor remain sweet. A perfect fermentation is when the whole of the saccharine matter and of the ferment are decomposed by their acting upon each other, being thus converted into alcohol. But it is sometimes desired to have the fermented liquor a sweet, vinous liquid. In that case the quantitv of ferment must be less than would be necessary to decompose the whole of the sugar, or the action of both upon each other may be reduced by some expedient, such as separating some of the ferment by a filter.

3014. *Fermentation probably commences somewhat sooner than it appears to do* by the bubbles of gas, which are the first indications; for the first carbonic acid gas that is produced in consequence of the process is absorbed by the water of the fermenting liquor, and it is only when the liquid is saturated that the gas escapes into the atmosphere with the appearance of effervescence.

3015. *A certain degree of temperature is essential to the process of fermentation.* Substances cannot ferment if exposed to considerable cold; the vinous fermentation cannot take place at the freezing point, or 32°; at 50° it is languid; at 60° it is quickened, and at 70° is so rapid that there is danger of its passing into the acetous; but, again, if the heat be much more considerable, yet below boiling, fermentation cannot happen; thus too low or too great a degree of heat prevents this process from taking place, or arrests it if begun. As the fermentation of beer does not succeed if the heat exceeds 77°, this beverage cannot be made in very warm climates, and very cold ones would require much expense to produce sufficient artificial heat.

3016. *The heat excited by fermentation is one of its most striking phenomena.* Its cause is entirely unknown, but an increased temperature is frequently one of the results of the decomposition of bodies. It will not begin until the temperature is raised to a certain point; and the heat excited by it is in proportion to the bulk of the fermenting mass, and the rapidity of the process. If the heat generated by the process, joined to that of the atmosphere, arise to too great a degree, it is necessary to restrain it, lest the vinous should pass into the acetous stage, and this is often found necessary by brewers and distillers. In the making of wine, strong must will bear a higher temperature than weak must, as the alcohol which is produced has a power itself in checking the fermentation, and also of preventing the acetic process; but in too high a temperature the juice of fruits that contain too little of the fermenting principle is apt to absorb oxygen, and to become sour; and this is often the case in the making of sweet wines. The larger the quantity of liquor, the lower the temperature may be at the beginning, as the process itself generates much heat. When the fermentation languishes from deficiency of heat, it is easily augmented by introducing a stove into the apartment where the process is conducted, or by heating a portion of the fluid, and then mixing this with the mass; agitation will diffuse an equal temperature through the whole. It is very important during fermentation to guard the fermenting vessel against any irregularities of temperature from change of weather or other causes.

3017. *The effect of air on fermentation was long disputed, but is now better understood.* It was once thought that no fermentation could take place in vessels absolutely close; and that the reverse practice, fermenting for a long time in open vessels, was productive of much injury and loss, partly from the evaporation of the alcohol as soon as it was formed, and partly by the yeast becoming sour and putrid, and communicating these properties to the wine, or other fermenting liquor. But the fact, as now ascertained, is as follows: if artificial ferment be used, a perfect fermentation will take place in vessels, however closed from air; but if the natural ferment only is present, as in the case of the mere juices of fruits, fermentation will not occur, as is shown by some experiments by Gay Lussac, which we shall describe, unless air be admitted.

3018. *Gay Lussac's experiments on the necessity of oxygen to excite fermentation are important*, as showing how small a quantity of it is sufficient. He took a bottle of the must of the grape, which had already been preserved more than a year by Mr. Appert's method of excluding the air, and was still perfectly limpid: he decanted this juice into another bottle, which was then closely corked, and placed in a temperature varying from 60° to 86°. In eight days it had lost its transparency, fermented, and was changed into a vinous liquor, frothing like the best Champagne. A similar bottle of juice, that had not been thus opened and exposed to the contact of air, although placed in the same circumstances, exhibited no signs of fermentation. He next passed a portion of juice into a vessel filled with and inverted over mercury, and added to it a small quantity of oxygen gas; and another portion of juice he confined in a similar vessel, perfectly freed from air. The former fermented in a few days, but the latter gave no signs of fermentation, even at the end of forty days. Similar results were obtained in experiments on the preserved juice of gooseberries; and he found the same thing to hold with regard even to the juice of fresh fruit. He passed some entire grapes into a vessel over mercury, and added to them hydrogen gas repeatedly, with the desire of removing all atmospheric air; the fruit was then broken down by passing a wire into the jar, and the vessel was left in a temperature of from 59° to 68°. At the end of twenty-five days it exhibited no signs of fermentation; but this process commenced the same day in juice to which a little oxygen had been added, and was also rapidly excited in the former portions when a little of that gas was supplied.

Grape juice could not be made to ferment when the air was *completely excluded*; but, on admitting a very small quantity of oxygen, this gas was absorbed, and fermentation commenced, and continued independently of any farther contact of oxygen. But a solution of sugar, mixed with yeast, fermented even in closely-corked bottles, therefore without access of air; from which Gay Lussac concluded that there must be a difference between the natural ferment in the grape and the artificial ferment yeast. The application of these experiments is obvious, not only in the preparation of fermented liquors, but also, as we shall afterward see, in the preservation of vegetable and animal food.

Exposure to the air, therefore, or the presence of oxygen, is necessary to fermentation in the first instance; but it is only necessary at the commencement, and for a very short period; so that when once the process has begun, in the case of natural ferment or mere juices, it goes on in closed vessels: the reason of this is, probably, that the artificial ferment contains oxygen itself sufficient to begin the process, and in the case of natural ferment the very air contained in the wood of the cask is often sufficient.

3019. *It is certain that the carbonic acid which escapes during fermentation holds in solution a considerable portion of alcohol*, as is proved by a vessel of water placed near to the fermenting vessel absorbing alcohol, and being distinctly impregnated with it; and likewise by the intoxicating effect produced by the fermentative process on those persons who are much exposed to the fumes. The real loss of alcohol, however, from this cause, though important in a large manufactory, is not deserving of attention in domestic practice.

3020. *Several inventions have been made for fermenting in tuns* closed, instead of being open to the air, but their advantages are not very obvious, even in the large way, where the loss of alcohol may be considered as of most importance. Some suppose that the exclusion of the common air may prevent the liquor from passing into the acetous fermentation; but it should be recollected that while the vinous fermentation is going on, the whole surface of the fermenting fluid is covered with a stratum of carbonic acid gas, which effectually excludes the atmosphere; and it is only when the vinous fermentation has ceased that common air can come in contact with the liquor.

3021. *Fermentation is considerably influenced by the mechanical agency of the atmosphere, that is, by its pressure.* The pressure of the atmosphere retards it, and when that is removed it goes on more rapidly. If liquor to be fermented be put into a well-corked bottle, the fermentation takes place *in time*; but the process is very slow, because the carbonic acid formed during the process cannot escape; it is absorbed by the liquid as soon as it is formed, and this will go on until the liquor is thoroughly saturated with the gas; and then, there being no farther room for this gas, it cannot be generated, and the fermentation is suspended. Liquor in this state will be thoroughly impregnated with carbonic acid gas, and hence the briskness of bottled malt liquor. But if there be facility for the escape of the carbonic acid, the fermentation proceeds; and hence, if bottles are badly corked, the vinous fermentation continues until it passes into the acetous stage, the liquor becoming sour. In brewing in the large way, means have sometimes been contrived of regulating the rapidity of the fermentation by preventing, in some degree, the escape of the carbonic acid gas, and thus subjecting the fermenting fluid to the pressure of this gas.

3022. *The quantity of the fermenting liquor has also an effect upon the fermentation.* Chaptal observed that grape juice contained in a small cask did not finish its fermentation until the eleventh day, while a large tub, which contained twelve times the quantity, completed its fermentation in four days.

3023. *The temperature of the fermenting liquor is also influenced by the quantity.* The heat of the liquor in the cask just mentioned never exceeded 74°, while that of the large tub reached 94°. It is probable that the combination of the principles would be less perfect, and therefore the wine, on this account, would not be so good in the small vessel as in the large one; but the latter would have an advantage, that there being less heat produced, a smaller quantity of alcohol and aroma, upon which the excellence of the wine chiefly depends, would be lost by volatilization. The same observations apply to the fermentation of beer of any kind.

3024. *The fermenting liquor becomes specifically lighter as the fermentation proceeds,* a fact which is ascertained by an hydrometer, and this is called by brewers the *attenuation;* and they are in the habit of taking the specific gravity of the fermenting liquor frequently, in order to judge accurately of the degree to which the process has arrived, and regulating its management accordingly. The reason is this: the specific gravity of alcohol is much less than that of water, which forms the principal part of every fermenting fluid; that is, a certain quantity of alcohol will weigh less than the same bulk of water; of course, a quantity of alcohol and water will weigh less than an equal quantity of water alone, and the greater proportion of alcohol which the water may contain, the lighter the fluid will be. Now, as alcohol is constantly generating during the process of fermentation, it is easy to see that any certain measure of the fermenting liquor will get lighter as the process of forming alcohol proceeds.

3025. *The opinion we have stated, that sugar or saccharine matter is the only one capable of the vinous fermentation, may appear to be contradicted by some known facts.* Raw corn, which contains much starch and but very little sugar, is, when mixed with malted corn, found to ferment, and afford as much alcohol as if the whole was malt. Also, alcohol may be abundantly obtained from potatoes, which contain much starch and scarcely any sugar, without any other preparation than boiling them in steam, breaking them into a fine paste with water, and adding a little raw wheaten flour and yeast. From these and similar facts it might appear that starch may at once be converted into alcohol by fermentation, as well as sugar. The observations by Kirchoff threw great light on this subject. He found that neither gluten nor starch, when kept in hot water separately, became sweet; but when a mixture of these two substances was put into similar circumstances, the starch was converted into sugar. Here it is plain, therefore, that this conversion of the starch was in consequence of some agency of the gluten. In the cases above alluded to, of raw corn and potatoes, there is some gluten present, by the action of which the starch might be changed into sugar; and a very small quantity of gluten as a ferment is sufficient to produce this conversion into sugar. The mode by which raw grain is converted by germination into malt, which is a sweet substance, is a similar process; and the production of sweet wort by the brewer or distiller from raw corn is another instance; so is the sweet taste of bread. As soon as sugar has been formed from the starch by this means, it passes so rapidly into the vinous stage that the state of sweetness sometimes escapes notice.

Thus it appears that not only do vegetables which contain actual saccharine matter produce spirit, but those also which contain starch can be made to undergo the vinous fermentation, owing to the starch being converted into sugar, which we know it is capable of by several processes; and that this newly-produced sugar goes at once, and as soon as formed, through the vinous fermentation.

3026. *The nature of ferments, we observed*, was yet little understood; but it would appear that various substances are capable of acting as ferments, or exciting fermentation of some kind. This property appears to be possessed in the highest degree by vegetable gluten and vegetable albumen; but caseous matter, fibrin, and gelatin, carbonic acid, &c., have also this power in some degree. But the substance which is usually employed to excite the vinous fermentation is the only one that has yet been studied with much attention, and it is much more rapid in its action than any other. That an acetous ferment exists is evident from the acetous fermentation being soon excited in a cask in which vinegar has been made.

ACETOUS FERMENTATION, BY WHICH VINEGAR IS PRODUCED.

3027. We stated that if liquids which had passed through the vinous stage of fermentation were exposed to the air for some time, in a temperature between 40° and 80°, a new change took place, by which the alcohol disappeared, and was succeeded by an acid taste in the liquor. During this change a slight intestine motion is perceived; the liquid rises in its temperature about 10° or 15°; it becomes turbid, and floating shreds appear, which subside at length into a gelatinous-like deposite. After some weeks it becomes transparent, and is found to be converted into vinegar, which consists of acetic acid, water, and some impurities. This acid has been generated by this new fermentation; the alcohol produced by the vinous fermentation has been decomposed into its elementary principles, and a new arrangement of them has taken place.

3028. *Every liquor which has undergone the vinous fermentation is spontaneously and necessarily disposed to the acetous.* Accordingly, every vinous liquor continually tends to become vinegar, and is actually changed into it sooner or later, according to circumstances, unless this change be prevented by some cause that is an obstacle to fermentation in general.

3029. *The acetous, like the vinous fermentation, requires a peculiar ferment;* andt his is supposed not to be very different from the vinous ferment, although its nature is very imperfectly understood: it would seem, likewise, to be some modification of gluten. The same yeast which excites the vinous fermentation in malt wort will also run the liquor into the acetous stage, if not prevented, but the matter which subsides in the making of vinegar is the most active in exciting the acetous fermentation. A cask in which vinegar has been already made will promote it, and fermented liquor can be converted in vinegar sooner in that than in another. But there is this difference between the vinous and the acetous ferments, that yeast, or the vinous ferment, is capable of exciting both the vinous and the acetous fermentations; but the proper acetous ferment can only excite the latter of these.

3030. *The theory of the acetous fermentation has been stated as follows:* during the process some carbonic acid is given out, which is supposed to be generated by the oxygen of the atmosphere combining with some of the carbon of the alcohol which is decomposed; and it is thought that vinegar, or the acetic acid, is formed at the expense of the alcohol. Alcohol by itself, as has been shown, is indestructible when pure; but when diluted with water, and mixed with vegetable matter, such as gluten, starch, sugar, or mucilage, it finds among these a ferment, which soon converts it into the acetic acid by a new arrangement of principles.

3031. *From these statements, we see that all substances capable of the vinous fermentation may pass into the acetous,* and do so naturally; but it would appear that some also acetify without apparently undergoing the vinous fermentation, and this occasions some obscurity in the theory.

3032. *Dr. Turner, in his System of Chemistry, has made a distinction that is very important.* The acetous fermentation, and the mere production of acetic acid, have been generally confounded together in books, whereas it is well known that although acetic acid is always the result of the peculiar fermentation that bears its name, yet this acid is often produced by the decomposition of vegetable substances, without any fermentation whatever. Mucilaginous substances, in particular, even when excluded from air, gradually become sour. Gum water sours without exhibiting any of the ordinary signs of fermentation. Weak ale, and beer, and wine, acquire acidity frequently, even in bottles well corked. These, and many similar processes, appear to be effected by a particular change of affinities, and are not attended by that visible movement in the liquid, with absorption of oxygen, disengagement of carbonic acid, and the other phenomena which accompany the acetous fermentation; to which we may add, that acetic acid is produced by the destructive distillation of vegetable matter in close vessels. The term acetous fermentation, therefore, instead of conveying the idea of taking in all the cases of the production of acetic acid, ought to be limited to the conversion of alcohol into this acid. That this change does really take place is inferred, not only from the disappearance of alcohol, and the simultaneous production of acetic acid during fermentation, but also from the quantity of the latter being precisely proportional to that of the former.

3033. *Of the three most important substances concerned in fermentation,* sugar, mucilage, and gluten, or the ferment, it would appear that the first is most disposed to undergo the vinous fermentation, and to produce alcohol; the second is extremely liable to change into the acetic acid, without apparently going through the vinous fermentation; and the gluten, if it does not act upon the sugar in producing the vinous fermentation, is most disposed, like animal matter, to pass at once into the putrid state.

3034. It would appear, also, that in some cases the acetous fermentation goes on, in a small degree, along with the vinous fermentation, and of course produces some acetic acid with the alcohol. This is evident in the distillation of malt spirits, where an acid is found to be left behind, which can have no other origin than the acetous fermentation, there being no natural acid in the malt. A part of this acid combines or unites with the spirit during fermentation; the other part remains behind, mixed, not combined, and such part as is more volatile rises with the spirit during distillation.

3035. *The presence of alcohol retards the acetous fermentation:* hence strong wines, and similar strong liquors, acetify with great difficulty, and bottled strong wines do not readily become sour. But when at last strong wines do acetify, they afford a stronger vinegar or more acetic acid than weak ones; however, in this case, the acid is not entirely supplied from the alcohol, for the mucilage of the wine contributes its share. Adding sugar during the souring increases, instead of diminishing, the quantity of acid.

Sect. IV.—Alcohol.

3036. We have mentioned that alcohol is the chief product of fermentation, and that it is the intoxicating principle in all fermented liquors; but it is never produced in a free state by this process. It is, at first, always mixed with water, mucilage, and some other of the constituent principles of the vegetable matter fermented, and from which it has been procured, as is the case with respect to wine, ale, or beer.

3037. *We likewise stated that pure alcohol is exactly the same from whatever vegetables it has been produced* by the process of vinous fermentation, all that is necessary being that they should contain saccharine matter. For this purpose, a vast variety of saccharine vegetable substances are employed in different parts of the world, each country making use of those which it has in greatest plenty, in order to produce a fermented liquor. Thus, in the south of Europe, the grape is chiefly used; in the East Indies, the juice of the palm affords an intoxicating beverage called toddy; in the West Indies, the sugar-cane supples rum; with us, malted corn is the chief material. After the alcohol has been formed by fermentation, another process is necessary to separate it in a pure state from the substances with which it is combined in the fermented liquor; and this process is *distillation*, for the nature of which, see Book VIII., Chap. VIII., Section 3, "Distillation."

3038. *When the produce of fermentation is distilled,* the spirit, being extremely volatile, rises in vapour, and is condensed by cold into a liquid: this, however, is not pure alcohol, for a quantity of water and other impurities rise with it. It is necessary, therefore, that this should be re-distilled, and go through other operations before it arrives at that state in which it is called rectified spirit, or common spirit of wine, the purest condition in which it is manufactured on a large scale. By another distillation it becomes *rectified spirit of wine.* But this still contains some water, which must be separated in order to obtain *pure alcohol,* which, however, is never employed in beverage; it is only required by chemists for pharmaceutical compounds, or for experiments and other nice purposes.

3039. *The method which chemists usually employ to get rid of the water* to procure alcohol is to mix the rectified spirits with a quantity of carbonate of potash heated to redness to expel all its moisture. This salt has a strong attraction for water, and the greatest part of it is insoluble in alcohol. It, accordingly, combines with the water of the spirit; and the solution thus formed sinks to the bottom of the vessel, and the alcohol itself, which is lighter, swims over it, and may easily be decanted off; or, what is perhaps better, the solution of potash may be drawn off from below it by means of a stop-cock placed at the bottom of the vessel. The alcohol thus obtained contains a little pure potash dissolved, which may be separated by distilling it in a water-bath with a very gentle heat. What now comes over is alcohol very nearly pure. Instead of carbonate of potash, substances having a strong attraction for water may be employed to purify alcohol; for instance, muriate of lime. The specific gravity, as usually obtained, is 0·800; but by great care, alcohol has been obtained so low as 0·796, at the temperature of 60°, that of the least specific gravity being always the purest, as having the smallest quantity of water; equal quantities of water and alcohol constituting what is called proof spirit, the specific gravity of which is 0·917.

3040. *The properties of pure alcohol are the following:* It is perfectly colourless and limpid. It has a burning taste, and peculiar, rather agreeable odour. It is highly volatile, and it boils, or is converted into vapour, at 176°; consequently, it is easily separated from water by distillation, as the latter does not rise into vapour till heated to 212°. Like all volatile liquids, it produces a considerable degree of cold when any body is wetted with it, on account of its rapid evaporation: if the finger be dipped in it, on drying, the cold will be felt. It has been found impossible, hitherto, to freeze it with the greatest degree of cold that can be produced: it has been tried by a cold 91° below the freezing point without rendering it solid; hence it is employed for constructing thermometers.

It is highly inflammable, burning with a lambent, yellowish-blue flame; the colour varying with the degree of strength, the bluish tint prevailing when its strength is greatest, and the yellowish as it is weaker. Its combustion is attended by no smoke, the only products being water and carbonic acid. When burning, it gives an intense heat, though the flame is so faint as scarcely to be distinguished in daylight. It unites with water in every proportion; and the union is attended with a slight diminution of bulk and consequent increase of temperature.

It acts as a powerful solvent on many of the substances belonging to the vegetable kingdom; hence it is extensively useful in preparing liqueurs for the table, and in many processes in the arts. The principal substances which it dissolves are *resin, sugar*, manna, camphor, balsams, essential oils, the vegetable alkalies, tannin, and extractive matter. It also dissolves the deliquescent salts; but generally those insoluble in water are so in alcohol.

Most of the acids unite with alcohol by the assistance of heat, and form the substances called *ethers*. Albumen and muscular fibre are not dissolved by alcohol; on the contrary, they are coagulated, hardened, and contracted by it; and milk is speedily curdled by it. It likewise dissolves soap, wax, and spermaceti.

3041. *When analyzed, alcohol is found, in* 100 *parts, to consist of* hydrogen, 13·64; carbon 68·18; oxygen, 18·18.

CHAPTER III.

BREWING.

Sect. I.—Introduction.

3042. *Brewing, or the art of preparing malt liquors*, was formerly considered as a more important part of domestic economy than it is in the present day, when the great increase of public establishments for this purpose has considerably diminished the necessity for private brewing. This, however, is chiefly confined to towns; in the country, many private families still brew their own beer, and there are many good reasons why this custom should still be adhered to.

3043. *In treating on this subject*, it might be perhaps expected that certain practical rules, founded on the best experience, should at once be laid down, exhibiting the perfection of the art. But, unfortunately, this is not possible. Not only are the best receipts for practice kept secret by professed brewers, but it does not appear that these are agreed among themselves respecting many important points. We are correctly informed by a writer in the "Library of Useful Knowledge,"

That the practical instruction for brewing ale and beer, as given by different "persons, are by no means uniform. The cause is obvious. The mode of manufacture, and, consequently, the quality, differ in every age and country; and, even in the same nation, the ale of one district has little resemblance to that of another." "He who has seen only one of the modes of brewing can have no conception of their number and variety. One shall mash three or four times, while another shall do so but once. A second shall pitch his tun at 80°

when others do so at 45°; the former cleansing in twenty-four hours, and the latter waiting three or four weeks for the finishing of the fermentation. One class of brewers attend chiefly to the attenuation, are minute in the heats of their fermentation, weighing the yeast with the utmost care; while there are many gentlemen (at the same time priding themselves on the goodness of their ale) who turn the worts into the barrels boiling hot, bung them up, and stow them for a year in their cellars, without any yeast at all. Each of these modes of brewing may be considered as producing a different species of ale; and each species has its varieties depending on natural or accidental circumstances, such as the water or the skill of the brewer, which add to its preservative qualities, and give certain adventitious flavours."

3044. *It is necessary, therefore, for every one who wishes really to understand the art of brewing to study its principles*, and not be contented with the mere routine practice of any one person or place.

3045. *With this view we have divided this treatise into two parts:* in *the first part* we shall describe the principles and operations of brewing, including a view of the chemical theory, as well as the general practice of the art, which we have kept together, so that one shall throw light upon the other: this we considered essential for those who are desirous of studying the subject scientifically. *In the second*, called "practical directions," we shall describe the practice only with all the minute particulars necessary to be observed. This separation we found necessary, since many persons may desire to see all the principal points to be attended to in practice, without going much into the theory; and had the whole been blended together, it would have been almost impossible to have distinguished the simple practical processes alone amid so much theoretical explanation; the theory would also thus have been encumbered with numerous fatiguing practical details. This arrangement has, indeed, rendered some repetition unavoidable; but we trust it will be found advantageous, although, without this explanation, it might have been thought unnecessary.

If the reader has perused with attention the article "On Fermentation," it will assist him much in comprehending what we shall say on this subject.

3046. *Brewing has been often practised successfully by persons who possessed no scientific knowledge*, and excellent beer and ale have been made in various parts of the country by our ancient dames, to whom the name of science was scarcely known. It might therefore be doubted whether there is any advantage to be expected by considering the subject in a scientific manner. The reply to this is easy. No theoretical knowledge can wholly supply the place of that which is the result of experience; but it may materially assist it, and more particularly with those who have had but little practice, to whom a work such as the present is chiefly addressed. An acquaintance with the theory of any process prepares the operator for his various operations, that may be regarded in the light of so many experiments, which, by this, he will understand and pursue with more certainty and intelligence. He is likewise by these means enabled to avoid many errors to which those unacquainted with principles are liable, and likewise the waste which they frequently occasion; an acquaintance with the scientific principles of an art renders the practice of more easy acquirement; and it is deserving of attention that the experience gained in this manner can be transmitted to others with greater facility. By connecting practice with theory, the latter being the knowledge of causes, an art is elevated, and may be rendered highly amusing, instead of its being, as it otherwise would, mere drudgery.

3047. Fifty years ago, brewing, both public and private, was in a very rude state. The first attempt to reduce it to scientific principles was made by a skilful brewer, Mr. John Richardson, to whom the art is much indebted, and to whose example we owe the present race of scientific brewers; but the modern discoveries in chemistry have likewise of late been successfully applied to the improvement of this art, which really involves some of the most curious and interesting phenomena in nature, and which has been considered to deserve the attention of some of our greatest philosophers.

3048. *It has been supposed that brewing on a large scale is necessary to produce good malt liquor.* This, however, appears to be an error; and though there are some difficulties in private brewing which are experienced in a less degree by manufacturers, yet there are some advantages in the former. Mr. Donovan observes that less heat is excited during the fermentation of small than of large quantities; and there is less danger of over attenuation, which renders the liquor liable to pass into acidity. When some of the fermentable matter is left unexhausted, it undergoes a slow and long-continued fermentation in the bottle, during which it mellows and becomes highly vinous. The great brewers, accordingly, have, in consequence, often fermented in small quantities; and Mr. Donovan, as well as other chemists who have paid attention to the subject, farther states that, from his own experience, malt liquors are best made in this manner in point of briskness, soundness, and body.

3049. *The economy or saving in domestic brewing* is, perhaps, not considerable; though, from calculations which have been published, the cost of beer should not be so great as when purchased from the brewer. But we are not to suppose from this difference in price that the brewer's profits are exorbitant; for he must have to pay for extensive premises, a very numerous establishment, and very costly apparatus; and out of this, too, the publican must have his profit. But economy is not the only advantage in domestic brewing. Good malt and hops are the only materials that we can depend upon, in general, for making sound wholesome beer; and it is by domestic brewing alone that the genuineness of beer can be secured. There are many public brewers, no doubt, who use only the legal ingredients, malt and hops, in brewing; but it would appear that, before the beer or ale arrive at the consumer (unless common report in this instance deserves no credit), either improper substitutes are used in part for these materials, or some of the dealers adulterate these beverages; and it is well known that many of the articles employed for this purpose are of an extremely deleterious nature. Nothing is more usual than for persons to express their preference of *home-brewed beer*, which would not be the case were it not really of a superior quality. Home-brewed beer is, in fact, if properly made, excellent in every respect. It spontaneously becomes transparent, and requires no addition for fining: it is also particularly calculated for bottling.

3050. *It has been stated, very erroneously, that cottagers* and others could buy beer at a lower price than they could make it at, since large quantities are made cheaper than small. Here the brewers' and the publicans' profits have been forgotten; the labourer saves all these, and, besides, the women can do this work.

Before we proceed to lay before our readers the principles of the art of brewing, it may be useful to give a sketch of the general process.

3051. *Outline of the general Process of Brewing.*—The term *brewing* is confined to the art of preparing from grain the fermented beverages called *malt liquors*, such as *ale, porter*, and *beer*. Grain, of itself containing too little saccharine matter to produce the vinous fermentation, is made to go through a process by which the quantity of its sugar is much increased, and by which it is converted into *malt*, the substance from which the term malt liquor is derived. An infusion of malt is then made with water, at about 170°; this is termed *mashing*, and the extract so produced is called *wort*. This wort, containing much saccharine matter in solution, might now be fermented; but the produce of such fermentation, though it would contain spirit, and be a kind of ale, would very soon turn sour, on account of the great quantity of mucilage and starch in the liquor, which would pass rapidly into the acetous fermentation. To precipitate these substances, and thus destroy one of the chief causes of the injurious change which would otherwise take place, as well as to communicate a more agreeable flavour and taste, *hops* are boiled with the wort; the hops contain some tannin, an astringent principle, which, combining with the mucilage, causes it to coagulate and separate, thus enabling the beer to be longer kept; and they possess, likewise, an aromatic flavour, which they communicate to the liquor, and cover its sweetness. The wort, after having been impregnated with the hops, is now thrown into large shallow vessels, called *coolers*, where it is cooled to about 50° as quickly as possible, before it has time to get sour; it is then submitted to the process of fermentation, after having been mixed with some yeast, which, by the vinous fermentation, produces alcohol or spirit in sufficient quantity to give the required strength to the liquor; at the same time, a portion of undecomposed saccharine matter, and of the mucilage, still remain, and assist in giving the peculiar taste which is essential to constitute good malt liquor. But if the liquor was allowed to remain in the fermenting vat until the fermentation was quite finished, there would be great danger of its passing immediately into the acetous stage; therefore, as soon as it has fermented sufficiently, the new-made beer is transferred into barrels or casks with bung holes, in which the fermentation is finished in a slower manner. During this *slow fermentation*, which is technically termed *cleansing*, the remainder of the yeast works out through the bung holes, and some coagulated lees settle to the bottom, leaving the beer clear. If it be not then quite transparent, it is rendered so by the operation of *fining;* and sometimes it is racked off into other casks, or bottled.

3052. This sketch of brewing will prepare the reader for understanding the enlarged descriptions of the several processes which follow.

Sect. II.—materials for brewing.

Subsect. 1.—*Malt.*

3053. Although in domestic brewing it might be thought sufficient to point out the qualities of the various kinds of malt as made by the maltster, since the preparation of it from barley is seldom attempted by private individuals on a small scale, yet, in accordance with the plan we have proposed to follow through this work, of teaching the *principles* as well as the practice of the various domestic arts, we feel it necessary to give a short account of the manner of preparing the malt, or, as it is called, *malting*.

3054. *The important part which saccharine matter acts in the vinous fermentation*, and, consequently, in producing the spirituous part of beer, has been already explained under the article "Fermentation."

3055. *Sugar of some kind occurs very generally in vegetables*, though not always in sufficient quantity to be recognised by the taste; and a small quantity is even discovered by the chemist in the farinaceous seeds, or corn. But, as we have shown, *starch*, called also *fecula*, is another very important principle, existing ready formed in vegetables. It is found in very large quantity in the farina or flour of various kinds of grain, particularly wheat, and in certain roots, as potatoes, arrow-root, &c. It is a curious and in teresting fact that starch is often converted into sugar by nature, and that this natural process can be imitated by art. We shall presently see that this change is effected during the time that the grains of corn begin to germinate or grow. The sugar of starch is, however, not so sweet as that of cane sugar, though equally capable of affording alcohol by fermentation.

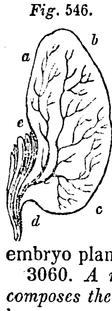
3056. *We may perceive, from these facts, that sweetness alone is not the only test of a substance being fit for fermentation;* one that is not sweet, but which contains starch, can likewise be fermented. This discovery, which was made not many years since, has thrown great light upon some circumstances in brewing that otherwise would prove extremely puzzling, particularly that of the ready fermentation of unmalted barley. The fact is, that raw barley does contain a portion of saccharine matter, as is evident from its analysis; the use of malting is only to increase this quantity by a conversion of its starch into sugar, which actually takes place, as also during the process of brewing previous to the vinous fermentation.

3057. *Barley is the grain almost always employed in Britain* for the purpose of the maltster, being superior to any other corn we possess; but every kind of grain, with scarcely any exception, might be used upon occasion by the brewer.

3058. *The preparation of malt is chiefly to procure a cheap sort of sugar;* but the other principles in the barley also assist in giving their peculiar qualities to the beverages called *malt liquors.* The mode of increasing the saccharine matter in barley is by taking advantage of the process which nature always performs when seeds begin to germinate or grow; but, to render this intelligible, we must describe the nature of germi nation itself.

3059. *Seeds, when planted in the ground, will not germinate except there be moisture* and a certain degree of temperature, which must always be above the freezing point and below 100°; likewise, they must not be entirely excluded from air. The seeds of vegetables consist of two essential parts: the *germe,* that part endowed with the principle of vitality, and the rudiment of the future plant; and of the *cotyledons,* or *seed lobes,* which contain the matter designed to serve for the nutrition of the embryo, or young plant, in the commencement of its growth, and before it is able to extract nourishment from the soil; the whole is included under a skin, called the *cuticle.* In the germe two distinct parts are discoverable: the *radicle,* or little roots, which, in germination, descend into the earth; and the *plumula,* which rises upward, and forms the stem and young leaves. When seeds are planted, or placed in circumstances favourable for their germination, they absorb moisture and swell, the membranes which cover them burst, the radicle shoots downward, and, at the same time, we perceive it sending out minute vessels into the farinaceous part of the seed, for the purpose of extracting nutriment to supply the plumula, or young bud, when it begins to grow. This commencement of germination may be easily examined by pulling up seeds that have been lately planted, and a little before the leaves appear above ground; and they should be looked at in various stages of their growth. To see the minute vessels mentioned, which the radicle sends into the seed lobes, a large seed, as a bean, should be chosen; and the annexed cut will exhibit the appearance of it. *a b c, fig.* 546, is the external membrane, or cuticle; *d* is the radicle; *e,* the plumula: the substance within the cuticle contains the nutriment of the embryo plant, which is seen sending into it ramifying vessels.

Fig. 546.



3060. *A remarkable change at this period of growth takes place in the substance which composes the mass of farinaceous matter in the seed.* Though originally almost insipid, it becomes sweet; in fact, a large portion of the starch in the farina has been converted into saccharine matter, evidently for the nutriment of the young roots which have shot out; when these have acquired size and strength enough to find their way into the soil, so as to extract their food from the earth, and the young plumula appears above ground, this first supply from the farina is exhausted, and then nothing of the seed remains but the skin.

3061. *It is this very curious natural process, this conversion of the starchy matter of the seed of the barley into sugar* by the means of germination, that is brought on artificially in the art of malting, on which chiefly depends the preparing of fermented liquors from farinaceous grains.

Malting is, then, a method of causing barley to germinate when moistened and laid in a heap above ground, by which a great quantity of saccharine matter is produced; and after this, and before the young plant has begun to reduce the saccharine matter by feeding upon it, the process of nature is stopped through the application of a sufficient degree of heat.

3062. *The following is the process of malting barley:* Malting consists of four distinct operations, which follow each other in succession, *steeping, couching, flooring,* and *kiln-drying.* Barley intended for malt should be of the kind that is largest, heaviest, and thinnest skinned. It should be perfectly sound, but need not be of the fullest kind. It should be all, if possible, of one growth, and not mixed, as grain of different kinds will not malt so equally together as if the whole was of the same sort. It is better also not to be quite new, but to have been in store for some time.

3063. *Steeping.*—The whole of the barley intended to be malted is put into a cistern lined with stone or slate, and water is poured upon it as many inches above the grain as it is expected to swell. The grain now imbibes moisture, and increases in bulk. A small quantity of carbonic acid is evolved, but does not rise in bubbles, as it is absorbed by the water, and may be discovered from the latter becoming milky if a little of it be mixed with lime-water. The steep water gradually acquires a yellow colour, and the peculiar smell and taste of water in which straw has been steeped; the barley at the same time becomes whiter, clearly showing that the water has absorbed a portion of the colouring matter that existed in the husk of the grain. Dr. Thomson observes that this yellowish colouring matter, when procured dry, by evaporating the water, has a disagreeable bitter taste, and contains a little nitrate of soda. This water is sometimes removed and replaced by fresh water.

After remaining in steep from forty to fifty-five hours, it is judged by the maltster to be sufficiently softened when the two ends of the grain can be easily squeezed together between the finger and the thumb. The water is then drained off, and the barley is removed to the malt floor to be couched. The increase of weight by steeping is considerable, but under twenty per cent.; when greater, the acrospire will have grown too much, and there will be a loss of saccharine matter.

3064. *Couching.*—It is now distributed on the floor in regular, rectangular heaps, about thirty inches deep, sometimes enclosed by boards, called *couch frames*, and in this situation it is allowed to remain for about twenty-six hours. If, some hours afterward, we plunge a thermometer among the grain, no increase of heat will be perceived; but at last the thermometer begins to rise, and the temperature of the grain will be observed to continue increasing until it is, on an average, about 10° above that of the atmosphere, which usually happens in about ninety-six hours; this increase of heat will be perceived by thrusting the hand into the heap. It now exhales an agreeable and peculiar odour, somewhat like that of apples.

The grain, which had become dry on the surface, now begins again to exhibit the appearance of moisture, called by the maltsters *sweating*, which is the first sign of germination. But it is requisite that this does not proceed too rapidly, which it would do were the heat allowed to increase still farther; and if the heaps were suffered to remain as at first, the heat would be greater in the centre than at the edges, which would cause the germination to proceed unequally. To prevent this, the maltster turns over the heaps with wooden shovels, and spreads it out in thinner heaps. The turning is repeated twice a day, and each time the heaps are made thinner and thinner, until at last they are reduced to three or four inches. The temperature which the maltsters wish to preserve is from 55° to 62°, according to the kind of malt they wish to make; but if not checked it would rise to 70° or 80°, and would at length actually char the grain.

But it is from the growth of the rootlets and plumula that the maltster ascertains when the germinating process has advanced as far as it is prudent to allow it. If we examine the grain soon after the commencement of the sweating, we shall perceive the roots beginning to make their appearance, at first as a white prominence, which, as it advances, divides into two or three, or more. These rootlets sometimes increase in length with great rapidity, even an inch or two in one night, except their growth be checked. About a day after the sprouting of the roots, the other part of the germe, the plumula, or embryo stalk, which is to produce the future stem and leaves, begins to shoot: this is called the *acrospire*. It rises from the same extremity of the stem with the root, and, advancing within the husk or skin, would at last (if the process were suffered to continue long enough) issue from the other extremity in the form of a green leaf; but, for the reason already mentioned, the malting is stopped before this takes place.

As the acrospire shoots along the grain to arrive at the opposite end, the kernel or mealy part of the corn undergoes a remarkable change. The glutinous and mucilaginous matter in a great measure disappears; the taste has become sweet, the colour white, and the texture is so loose that it easily bruises or crumbles to powder between the fingers, and this change is considered to be sufficient when the acrospire has come nearly to the end of the seed, and is just ready to burst out.

The object of the maltster is now accomplished; the farinaceous matter has become more soluble in water, much saccharine substance has been produced, which very readily undergoes the vinous fermentation. Before the acrospire has reached the end of the grain it is considered that a part of the fecula of the grain remains unconverted, hard, and insoluble; and if the acrospire be suffered to grow to a great length, then a portion of saccharine matter has been lost by the germination, having been employed as the food of the young plant. It may be observed that in the smaller kinds of barley, and in bere or bigg, it is considered that the acrospire should not be allowed to grow above three quarters or four fifths of the length of the grain, as more than that will diminish the saccharine matter. With respect to the actual nature of the change which takes place, there is still some obscurity in the subject, and the best chemists are in doubt respecting it; it does not appear to be understood whether all the actual sugar is formed in malting, or whether much of the starch has only undergone such a change as disposes it to be easily converted into sugar by the hot water during the next brewing process, the mashing. The difference is very interesting in a speculative point of view, but less so in practice; for, however the case may be, we are certain that such a change is brought about by the process of malting; that barley which has been malted furnishes a decoction called sweet wort, much more capable of undergoing the vinous fermentation than one made from raw barley alone.

The time required for the grain to continue on the malt floor must vary with circumstances; the higher the temperature the sooner the germination arrives at that point when it must be altogether stopped by being dried in the kiln. In general, the operation of couching occupies fourteen days. In certain cases, where it is desired to have a milder but more viscid ale, the germination is not carried so far, and the time is shortened. Malting cannot be performed with any success in the summer months, and the best maltsters prefer cold weather; in winter they can always keep the germination at the rate they wish by heaping up the grain, whereas in warm weather it grows so rapidly that no effort can keep the process equal and regular.

3065. *Kiln-drying.*—By this process all farther vegetation is completely checked, and the malt is dried so as to enable the brewer to keep it for some time without injury. The mode of drying malt is a matter of great nicety, and there are various constructions of the floors of the kiln or chamber in which it is spread. Some are made of wire net-work or hair cloth; others are formed of earthen-ware tiles, or iron plates perforated with innumerable conical holes, very small at the upper surface, and much wider beneath. In the roof there is an aperture to permit the escape of the heated air and vapour. The malt is spread out on this floor about four inches in thickness, that it may dry equally; and beneath there is a large fire of charcoal or coke, the heated air from which ascends through the holes in the floor, passes up through the malt, and makes its way out through the roof, carrying the moisture along with it. The heat should be very gentle at first, not higher than 90°, and should be raised very gradually till it reach 140°.

Dr. Thomson informs us that he has seen malt dried at a temperature of 175° without becoming brown. The great secret in drying malt properly appears to consist in keeping the heat very low at first, and only raising it *very gradually* as the moisture is dissipated. It would seem that the less heat that is employed the better, so that the germination is completely stopped, and the malt is thoroughly dried, so as to keep well. The grain, which at first was hard and cohesive, has become friable like a mere body of flour, and is so easily divisible that, when properly managed, a mark may be made with the kernel like a bit of chalk. At the high degrees of heat sometimes used, much of the saccharine matter is decomposed and lost; and, in some places on the Continent, malt is at present dried only by the air without any fire. The degrees of heat employed give different properties to malt, and hence we have various kinds which are used for different purposes.

Pale malt is dried with the lowest heat, and its colour is not changed; it contains the greatest quantity of saccharine matter, and affords the strongest liquor; it is always used for ale, and now partly also for porter.

Amber malt is dried with a higher degree of heat, by which it is a little scorched; and it is less sweet, because some of the sugar has been a little altered.

Brown malt is still higher dried, and the scorching has gone so far that scarcely any taste of sugar is left. It is little used except for porter.

A malt of a deep brown colour, almost black, called *patent malt*, is prepared by roasting it in an iron cylinder in the same manner as coffee; the taste is very bitter, and its only use is to give colour to porter, for it is burned so much as to be incapable of fermentation.

The best fuel for kiln-drying is good coke or charcoal. Where it can be had, anthracite or non-bituminous coal is also used, such as the Kilkenny and Swansea coal, or culm: the fuel employed ought to give no smoke. Turf is used in some parts of Ireland, and this is best when prepared as coke.

When malt is sufficiently dried, it is suffered to cool slowly, and the sootlets are removed by screening; it is then spread out again to mellow, that is, to lose its crispness, and become soft and mealy, before it is ground in the mill for the brewer.

VARIOUS ADDITIONAL OBSERVATIONS ON MALTING AND MALT.

3066. So much of the knowledge and success in brewing depends upon the malt, that we shall enter into some farther details respecting the nature and properties of that substance.

3067. We are indebted for some of the following observations to Arthur Aikin, Esq., whose extensive knowledge of chemistry as applied to the arts renders his opinion highly deserving of attention: "In the conversion of barley into malt, a small quantity of carbonic acid is given off, and probably part of the starch is changed so as to become more soluble in warm water; the taste of malt is also sensibly sweeter than that of barley meal; and hence we may conclude that a portion of the starch is converted into sugar. A remarkable change also takes place in the texture or cohesion of the particles of the starch: in the raw grain they are compacted together, so as not easily to be broken down by the teeth, whereas grains of malt, when properly prepared, may be crushed with the greatest ease. The starch of wheat is soluble in water at the temperature of about 170°; that of barley appears to be soluble at perhaps a somewhat lower temperature. Now starch, when once dissolved in water, cannot be obtained afterward by mere evaporation in any other state than a hard, tough mass of difficult solubility, considerably resembling gum tragacanth. Hence it is peculiarly requisite, in drying malt, to apply at first a very gentle heat, for if, by an accidental forcing of the fire, or negligence in turning the grain, any portion gets heated to the temperature of 170° or 180°, the water and the starch immediately combine together, and no subsequent care in drying can prevent the grains so affected from becoming hard and perfectly useless to the brewer. Such grains, as well as those of raw barley, will sink in water, whereas those of well-prepared malt will float; hence our way of judging of the goodness of malt is to throw a little into water, and ascertain how many grains float and how many sink.

"If pale, well-dried malt be exposed to a gradually increasing temperature, it first becomes slightly yellowish brown, or pale amber-coloured; with an increase of temperature the colour increases, and, by proper care, it is very possible to bring the grains to a very dark coffee-colour without charring them in the least degree. In proportion as starch is charred, that is, converted into charcoal, it becomes insoluble in water, either hot or cold; but in proportion as it is exposed to an increasing temperature, provided such temperature is inferior to that required for charring, it becomes more and more soluble, and at last forms a perfect solution of the colour of clarified coffee, even when digested with cold water. This solution gives no indication with chemical reagents of the presence either of starch or of sugar; it will remain for months exposed to the air without becoming mouldy or turbid, and when evaporated, affords a brown gum perfectly resoluble in cold water. The sugar of the malt appears to be altered by heat before the starch is materially affected, and hence an infusion of brown malt is not sensibly sweet to the taste, and is not susceptible of fermentation."

3068. From this account it is obvious, that however the high drying of malt, so as to render it brown, may develop a soluble colouring matter, and a peculiar flavour, in the same manner as in coffee, and which forms some of the causes of the peculiarity of porter, yet it does this at the expense of the fermenting principle. Brewers have long ago found this out, and instead of using only malt dried *moderately brown* for porter, as was the case formerly, it is the general practice at present to employ *pale* malt for the purpose of the fermentation, and to add a certain quantity of *patent malt* for communicating the brown colour and flavour to which the public are accustomed in this beverage.

3069. The method of preparing the brown or patent malt was discovered by Mr. Wheeler, who took out a patent for it in 1817. The heat necessary to bring the malt to the degree of brownness proper for the required purpose is about 400° Fahr. Before the general adoption of this by the brewers, the operations of the maltster were considered of very great nicety in order to produce accurately the precise degree of drying necessary for various purposes; but the use of the patent malt renders the drying of malt an affair of much greater simplicity, as little more than pale malt is made in general.

3070. Malt that has been well dried by a long-continued low heat, not sufficient to alter its colour, and therefore called pale, will afford the most saccharine or fermentable matter, and, consequently, liquor of the greatest strength; it is also the only malt fit for brewing ale, since it does not give that acerbity of taste which is the consequence of rendering the malt brown, but which occurs in porter, and which porter drinkers prefer.

3071. According to Dr. Thomson, barley loses about 8 per cent. by being converted into malt, of which 1·5 is carried off by the steep water; 3 is dissipated on the floor; 3 consists of rootlets separated by cleaning; and 1·5 is waste.

The following is a comparison of the analysis of unmalted and malted barley, showing the changes that have taken place in the operation, particularly the diminution of starch and increase of saccharine matter:

Dr. Thomson.

	Barley.	Malt.
Gum - - - - - -	5	14
Sugar - - - - - -	4	16
Gluten - - - - -	3	1
Starch - - - - -	88	69
Total - - - -	100	100

Proust.

	Barley.	Malt.
Resin - - - - - -	1	1
Gum - - - - - -	4	15
Sugar - - - - - -	5	15
Gluten - - - - -	3	1
Starch - - - - -	32	56
Hordein - - - - -	55	12
Total - - - -	100	100

3072. According to Proust, barley contains a peculiar principle which he has named *hordein*, and which has hitherto been confounded with starch; part of this hordein he supposes to be converted into saccharine matter, and part into a kind of starch possessing some properties different from the starch of barley: but this new view of the subject does not appear to be sufficiently established.

Malt may be preserved good, in a proper situation, for a whole year or more, if guarded from moisture; and it should not be too much secluded from air. If barley be subjected to the same temperature as in drying malt, it loses only 2 per cent., which is, probably, only water.

Excellent malt can be made from *oats*, which, when mixed with barley malt, affords a sprightly sweet drink; raw oats, well dried, not malted, would answer mixed with malt, and is permitted by the excise to be used in private, though not in public brewing. *Wheat* does not afford a malt so sweet as that from barley, and is not allowed in this country by the excise laws, but it is much employed on the Continent; in the Netherlands and Prussia they employ five parts of malted wheat mixed with one part of malted barley, particularly in making the white beer of Berlin. In India they make malt from *rice*, and the spirit produced from it is called *arrack*. The Chinese employ *millet* for a similar purpose. The malt from *rye* is said to afford more spirit than that from barley.

Malt is also made from *maize*, or Indian corn, and in the Philosophical Transactions we have an account of the mode of preparing it. It appears that it will not succeed in the usual manner; and that it must actually germinate in the earth. To effect this, the soil is removed from the surface to the depth of a few inches, and the maize sown quite thick upon the ground; the earth is then replaced over it, and in ten or fourteen days the shoots come up, and present the appearance of a green field; the germinating corn is then taken up, freed from the soil, and dried. This malt is very sweet, and makes a beer very pleasant and wholesome. Mungo Park informs us that in Africa the negroes prepare beer from the *Holcus spicatus*, and that the process which they employ seems to differ but little from that followed in this country; it is here worth recollecting that beer is said to have been invented by the ancient Egyptians. In all these cases it is obvious that the principle is the same; the germination of the various farinaceous seeds in malting produces sugar, the only material capable of the vinous fermentation.

The colour of liquors made from malt, when no colouring matter is used, arises from a degree of decomposition during the drying by fire; for if malt was dried in the sun, as it was formerly, the liquor made from it would be nearly colourless.

When malt is of the best quality, and well prepared, the grains should be large, clean, plump, well filled with flour, and not shrivelled, the skin thin. The grains should break easily when bitten asunder, and have a floury kernel that should give a trace like chalk: its taste should be sweet and mellow, and leave no impression of rawness, but should feel soft and mealy between the teeth, whereas raw grain is tough, and not easily broken: if the malt be hard and flinty, it is bad: the colour should be clear, and there should be no disagreeable smell.

Malt is specifically lighter than water, and will swim, but unmalted grain sinks. To try if the malt be properly made, put a handful of the unground malt into a basin of cold water; let every grain be wetted all over, and, if good, they will swim on their sides: such grains as swim endways, or sink, are not properly malted. If only 5 grains in 100 sink, the malt may be considered sufficiently good. A bushel of malt will weigh about 40 lbs., and the dealer should guarantee its weighing so much; what weighs less is not good; a sack will weigh about 160 lbs.; the value is therefore determined by its weight.

3073. *Grinding the Malt.*—Malt is ground previously to its being used for brewing. It is found best, in general, not to grind it to meal, but only so that each grain is broken or cut into three or four pieces. If ground to a fine powder, it is apt to set into a paste that the water cannot penetrate; and, except every particle of malt be exposed to its action, the whole of the soluble part will not be extracted. In large breweries the malt may be ground finer, because the whole mash is agitated by machinery driven by a steam-engine, and thus the mashing is performed quicker and more completely; but in brewing on a smaller scale, where the agitation cannot be so perfect, it is proper to grind the malt coarser, that the water may be allowed to act for a longer time, and the wort drain away through the interstices.

The usual method of grinding is by a common flour mill with two circular stones placed one above the other, but at a greater distance than for flour; but this grinds very unequally, some grains being reduced to powder, while others have the husks scarcely broken. Steel mills that cut the malt with teeth, in the manner of coffee mills, are much used, particularly in private families, and they answer rather better: they have the advantage of being always ready, whereas a corn mill may be found only at a distance, and private mills form a security against any unfair dealing with the malt. Their price varies from three to ten guineas, but, except great care be used, they are apt to grind too fine. Some use a pair of revolving rollers made of case-hardened iron for *crushing*, instead of grinding the malt, a method which some consider as superior, though it is apt to compress the flour, and prevent the action of the water. Whatever method most completely opens the husk, without reducing the kernel to flour, and allows the water to extract most completely the soluble part of the malt, will be best adapted for brewing. The malt should not be kept above a day or two after it is ground, as it is then apt to heat and ferment, and, consequently, to clot into hard lumps, that not only require to be broken, but communicate a bad flavour: but it is thought useful to keep it a day or two in a cool place, secluded from the light, to *mellow*, which, they say, renders the soluble part more easily extracted.

SUBSECT. 2.—*Hops.*

3074. *This essential ingredient in malt liquors* consists of the floral leaves of a well-known perennial plant, commonly called the *hop vine, humulus lupulus* of botanists. The hop is diœcious, that is, the male and female flowers grow upon different plants, and are o a different form; the catkins, *fig.* 547, are picked and dried for the purpose of brewing. It is a native of Britain and most parts of Europe, and is seen occasionally flowering in our hedges in June, and ripening in September; notwithstanding which, its use in beer in England is not of great antiquity; when first employed here, it was introduced from the Netherlands. There is only one species of this plant, but there are several varieties of it, the qualities of which depend much upon the soil. The southern counties of England, particularly Kent, are celebrated for the mildness of their hops; those in the neighbourhood of Canterbury and Farnham are reckoned of the best quality for porter, uniting an agreeable flavour with strength. Nottingham hops, grown on clay, called *north clay hops*, are strong, but are thought to have a rather rank flavour; they are chiefly fit for liquor that is to be long kept. In Worcestershire and Cheshire a mild hop is grown very fit for ale. They are a very uncertain article of growth, frequently failing in bad seasons, a circumstance that has a material effect on the brewing of that year.

Fig. 547.

Hops are dried nearly in the same manner as malt. They are spread upon a hair cloth, from eight to twelve inches deep, and placed in the kiln, and a steady heat is applied for eight or ten hours, until the ends of the hop stalks are quite shrivelled and dry; they are then taken off and laid out on a large floor to cool. When quite cold, they are packed up in bags and sent to market. As the smoke from any fuel would be improper in drying malt, some kind that gives none is used; as coke, Welsh stone coal, or culm, or charcoal. If coal is the fuel, a contrivance called a *cockle-oast* is used.

3075. *Hops abound in a bitter principle*, which they possess in great perfection, and for which they are supposed to be chiefly employed; this is soluble in water, and is easily communicated to the wort in boiling; they likewise contain the *astringent principle, or tannin*, which is probably the most important one, by its precipitating the great quantity of mucilage contained in the wort, and which is the principal cause of beer turning sour. They contain also a *peculiar aromatic oil*, from which they derive the odour and flavour by which ale is distinguished, and which is very apt to be dissipated and lost by long boiling.

3076. *The ostensible use of hops in malt liquors* is the rich, aromatic bitter which they communicate, and which covers the sweet, mawkish taste of the liquor produced from malt alone, together with their power of preserving the beer from acidity. But there appear to be some doubts as to which of their principles this latter effect is to be ascribed. It appears to be an erroneous view of the subject to suppose that the preserving power of the hop resides entirely in the bitter principle; and hence to imagine that all bitter substances have a similar preserving power. It is the *tannin*, or *astringent principle*, that acts in this manner, by precipitating the mucilage of the malt; and many substances are extremely bitter without possessing tannin. Modern chemistry has likewise shown that there is no such thing as a uniform, unvarying bitter principle; but that the bitter of different vegetables is of a variable nature. Many of these are violent poisons. The cause of the bitter taste of the root of squills is very different from that of the hop; and many substances may communicate a bitter taste to liquor without having the power of coagulating mucilage, and thus preventing acidity. The bitter of some vegetables, instead of preventing acidity, is itself liable to become acid. On this account it is necessary to hesitate in admitting certain substances as substitutes for hops until the chemist has given us their analysis. At the same time, there is little doubt but many vegetables may be as useful in preserving beer, although they may not possess the peculiar aromatic flavour of the hop. Some of these will be mentioned in a subsequent part of our work. Dr. Paris states that "hops contain several elements of activity not in its substitutes. Its bitter principle is a tonic, its aromatic is warm and stimulant, and its astringent qualities precipitate the mucilage in the manner of tannin, and thus remove the cause of acid fermentation." Liebig is of opinion that the oil of the hops diminishes, in a great degree, the tendency of the alcohol to be converted into acetic acid, and therefore to preserve the beer.

3077. *The narcotic principle which they are known to possess* does not reside in the bitter, nor in the aroma, as some have supposed, but in a peculiar matter. A decoction of hops, like all narcotics, produces a little exhilaration, and is said to be stupifying; this effect is succeeded by depression. It is supposed that they add to the intoxicating property of the alcohol or spirit in beer, and the difference between wine and malt liquors in producing sleep is well known. It may be fairly doubted whether the constant use of a considerable portion of such a narcotic may not be prejudicial in certain constitutions, where exercise or much excitement is wanting to carry it off. Upon the whole, however, it is universally allowed that hops render malt liquors more wholesome than they would otherwise be, considering their great tendency to acidity.

3078. *Dr. Ives of New-York has discovered that the active principles of the hop do not reside altogether in the leaves of the flower themselves*, but chiefly in a fine yellow powder, which may be separated from the hops by beating and sifting. This powder, which he has called *lupulin*, forms about one sixth of the weight of the hops, and possesses the valuable properties ten times more than the leaves; it is well known to hop dealers, who call it *condition;* and they value hops in proportion to the quantity of it which they contain.

3079. *The best hops* are of a bright colour, between yellow and green; but if they are very green, they have been gathered too young; and when very brown, they have been allowed to ripen too long on the poles, or they are over-dried, and have lost their aroma, or peculiar flavour. They should have a powerful aromatic flavour, particularly when rubbed between the fingers, should feel clammy in the hand, and should possess much of the yellow powder above mentioned. Porter brewers prefer hops of a rather brown colour; but ale and table beer brewers use pale hops.

3080. *Hops do not keep perfectly good more than a year*, and therefore it is best to procure them of the present year's growth. They soon loose their essential oil, on which the aromatic flavour which they communicate to malt liquor depends; but they do not for several years lose their bitter and astringent principles. If they are more than a year old, but still fresh, they may, perhaps, require to be used in somewhat greater quantity: if they have not been well packed, they attract damp and become mouldy, in which case they are altogether useless. The close packing in bags is supposed to preserve them; old hops are generally reckoned to be one fourth or one fifth less in strength than new.

Subsect. 3.—*Water.*

3081. It is generally stated among the directions for brewing that it is absolutely necessary that the water should be quite soft, and that, if at all hard, it will not act sufficiently upon the malt, nor make good beer. Soft water, such as fresh rain water, or the water of a river or stream, is certainly the best, as being the purest; stagnant water is entirely unfit. But the hardness of water proceeds from certain salts which are dissolved in it (see Chap. I., Book VIII., "On Water"), and it does not appear that the small quantity of such salts is injurious to the process of brewing. Mr. Donovan states that "the grains and hops left after they have been duly infused in hot hard waters, repeatedly applied, are found to be perfectly exhausted of their qualities; and that as wormwood, gentian, quassia, and columbia give out their bitterness freely to water containing salt dissolved in large quantity, there is no reason for supposing that the same water would prove less efficacious with hops. It was formerly thought that good porter could not be made except with Thames water; but this is now known to be an erroneous idea. In fact, most of the principal London porter brewers do not use the Thames water, but have this liquid from deep wells which afford it soft, but still not so much so as that of the Thames. It may be considered, therefore, that many kinds of good drinkable fresh water will do for brewing, provided it be free from impregnations derived from stagnant pools or ponds containing decayed animal and vegetable substances. With regard to the objection that is often made to pump and well water, it is to be observed that these are not always hard, and when they are not so, they are generally very pure. An absurd notion has been stated by some persons that boiling bran in hard water will make it soft: this error arises from such persons not being acquainted with the theory of the hardness of water, or, in other words, with the true cause of that quality. We refer the reader here to Chap. I., Book VIII., "On Water," where he will find that salts alone are the cause of water being hard; and these cannot be in any way affected by the bran.

Sect. III.—PRINCIPLES FOR THE OPERATIONS IN BREWING.

3082. We shall now proceed to describe the general processes employed in brewing, at the same time *explaining the principles on which they depend*, but reserving the minute practical directions for a subsequent Section.

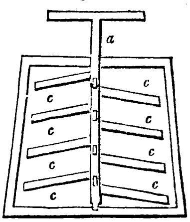
Subsect. 1.—*Mashing.*

3083. *The first operation in brewing is infusing in water*, or *drawing out the extract from the ground malt*, which extract is called the *sweet wort*, and contains all the saccharine and other soluble parts. This operation is termed *mashing.*

3084. *The heat of the water is a matter of very considerable importance;* but it is impossible to fix upon a degree that should always be employed without deviation, since the temperature must vary somewhat according to the kind of malt used, the sort of liquor required to be made, and various other circumstances which will be stated as we proceed. The heat of the water usually employed for mashing is from 160° to 180°, the best brewers generally using the lowest temperature. The water, at about this heat, is let into the mash-tub, and immediately after, the ground malt is let down upon it; or they are otherwise mixed, as will be seen in the description of mash-tubs. The malt being specifically lighter than water, it floats, and the whole requires to be well stirred together;

for if the malt were suffered to remain undisturbed, it would in time absorb water, and sink to the bottom, parting with its saccharine matter to that portion only of the water which is in immediate contact with it; hence agitation is found to be necessary for the purpose of bringing every particle of the malt into contact with fresh portions of water, and thus effecting a solution of the whole. This process was formerly performed in large, as well as in private breweries, by men who stirred up the malt in the water with long poles called *oars*, mixing the whole together in the most accurate manner, breaking all the lumps and clots, so that the water may have access to every part. In large breweries this operation is now effected by means of machinery. A vertical axis, *a b* (*fig.* 548), is fixed in the centre of the mash-tub, having horizontal wooden blades, *c*, *c*, *c*, projecting from it, which, being made to revolve, the blades succeeding each other break completely all the lumps, and prevent the malt from settling at the bottom. The saving of human labour by this means is very considerable, and the mashing is much more perfect. We have described this mode, which is one of the greatest improvements in the great breweries, not because it is absolutely necessary to do so, for it would very seldom, perhaps, be adopted in private brewing except on a very large scale; but because it is proper to know what is the most perfect mode of performing any process: the narrow wooden shovels, called oars, are all that are used in ordinary domestic brewing.

Fig. 548.



After the stirring has been continued for about three quarters of an hour, a cover must be put over the mash tun, to prevent the escape of heat, and the whole must be left quiet for the same length of time, about an hour or more, that the materials may react on each other, and likewise that the fine floury matter which had been mixed up with the water may subside; otherwise the wort, instead of being transparent, would run off muddy from the suspension of the fine particles.

3085. *It has been a common idea that during this time the water is merely taking up the soluble part of the malt;* but it is highly probable that another action likewise takes place, and that it is in the mash that a very large proportion of the starchy matter of the malt is really converted into that saccharine principle essential to fermentation, as we have stated already. This change appears not to be instantaneous, for the sweetness in the wort for the first ten minutes is inconsiderable, but it becomes gradually more and more so during perhaps two hours, notwithstanding the water is becoming cooler all the while.

3086. *Several facts appear to render it probable that the saccharine matter is not completely developed in the malt.* If cold water be left on malt for any length of time it does not become sweet, or very little so, and it will soon become sour; hence it is evident that the saccharine matter of malt is not soluble in cold water; but it is dissolved by hot water, and, once extracted by this, it remains always soluble, not only in hot, but likewise in cold water: it must, therefore, have undergone some change; and from this we see the necessity of mashing with warm instead of cold water.

3087. *Another fact proves that saccharine matter is formed in the mash tun* as well as in malting. It is now known that raw barley, if mixed with a certain quantity of malt, will give as sweet a taste to the mash as if the whole was malt, and can be made to ferment without being malted. This had long been secretly practised by the Scotch distillers of whiskey, with a view to evade the duty on malt, and, indeed, the expense also of preparing it. When the method was known to the brewers, it was resorted to by them also, producing an immense saving; but the practice was put a stop to by the excise. Private individuals are, however, at liberty to employ it for their own use. It is evident here that the effect produced upon a portion of malt is communicated to the starch of the raw barley, and this is supposed to be the result of a particular species of fermentation which we have already described as the *saccharine fermentation.* The formation of the sugar, therefore, begun in the malting, is completed in the mashing.

3088. *We shall now point out an accident to which mashing is very liable,* which it is absolutely necessary to guard against, and the nature of which cannot be comprehended without having recourse to those chemical principles which we are blending in our account. The accident to which we allude is called *setting* by brewers. When the water used for the mash is of too high a temperature, the whole often thickens and becomes of a pasty nature, which prevents the water passing through it, or the wort from draining off; in this case the whole mash is irrecoverably lost, the liquor remaining locked up in the paste. The cause of this curious phenomenon we shall now explain. We have already pointed out, that although the usual notion is that the whole of the starch of the barley is converted into saccharine malt during malting, yet that in fact only a part is so converted, and that, when the malt is ground for mashing, it still contains the greatest part of its starch slightly changed. Now it is a fact well known to every laundress that pure starch is not acted upon by water heated below 160°; but when the temperature of the water is raised to the boiling point, or nearly so, it then thickens into a gelatinous mass, from a combination with the water, which is the state in which it is brought for stiffening linen. The accident of *setting* in the mash is exactly analogous to this. It is owing to the water being heated to such a degree as is capable of *gelatinizing* the starch of the malt, or converting it into a stiff gluey paste, which prevents the water from penetrating into the body of it; consequently, it cannot have access to and dissolve the saccharine part. The nature of this danger being clearly impressed upon the mind, it will be easily perceived that we must take care that the mean heat of the mash, when mixed, should not be too great, otherwise we shall run a great risk of setting; this heat should never exceed 185° at the utmost; at 198° most kinds of malt afford a cloudy wort.

3089. *But there are some other circumstances to be understood before we can be prepared against all the accidents* and failures which may arise from an improper temperature of the water used in mashing. It is evident that, if hot water be poured upon cold malt, that the temperature of the water will be at once considerably lowered; but it is found that this lowering is not so great as if the water was poured upon raw barley ground: the fact is, that some heat (that of a few degrees) is generated by the mixing together of ground malt and water, which does not take place when raw barley is used. Every one must have observed that heat is often excited by the union of two cold substances, an example of which is seen in mixing oil of vitriol with water suddenly. Now, in producing the proper heat of the mash, allowance must be made for all this; and that might be done accurately, did all kinds of malt give the same increase of temperature; but this is not the case, for the heating produced by the malt depends in some degree upon the manner of preparing it. High-dried malt heats more than pale; and malt heats more or less in proportion to the temperature in which it has been dried. The heating from pale malt is very little, and may generally be neglected; but that from brown malt is considerable, amounting sometimes, it has been said, to 40°.

3090. *Another evil attends too hot a mash*, namely, a portion of extractive matter is taken up by the wort, causing a degree of cloudiness, which often attends the liquor through all the subsequent processes, requiring at last the use of fining in order to be got rid of.

3091. *On the other hand, there are several evils accompanying* too cool a mash. The conversion into saccharine matter will be incomplete; much starch remains unaltered; the wort so produced will be deficient in flavour, and be apt to turn sour before it runs off clear. It is more difficult to preserve a proper heat in mashing a small quantity than a large one, because in the former the heat is soon dissipated, and the mash is apt to cool too much before the fermentable substance is extracted; hence it is necessary with small quantities to employ as much heat as may be consistent with other circumstances. Sometimes it is necessary to increase the heat of the mash, which may be done by pouring boiling water into a pitcher or tin pail, and immersing the vessel partly in the mash, but not so deep that the water can escape into it; the heat of the boiling water coming through the pail will warm the mash.

3092. *After the mash has continued* the proper time it is run off by a stop-cock, or spigot and faucet, into a vessel placed below to receive it, called the *under back;* this is, in the brewer's language, called *setting the tap*, a phrase probably borrowed from the old and simple fashion of letting off the wort from the mash tun by a tap tree placed in the bottom. This draining off the wort, which, if the brewing be considerable, is best effected by a stop-cock, requires to be done with caution, lest the grains in the mash tun should be disturbed, and choke up the holes in the bottom. To avoid this, which would prove very troublesome, and risk spoiling the brewing, the stop-cock should be opened at first very little, and care should be taken that the wort runs clear; if it comes off foul, what has been drawn should be returned gently into the mash-tub, and a little time allowed to elapse till it is found to run quite clear; as soon as this is the case, the whole, or all that is required, should be drawn off; but the clearness of the wort is essential.

3093. It must be observed, however, with respect to the term *clear*, that, with all the care possible, the wort never flows from the mash tun absolutely transparent and bright, but there is always a dulness, which is to be removed by the next operation, the *boiling*. The cloudiness which the wort sometimes will, after all, retain, is frequently, no doubt, owing to the water having been too hot, by which it has dissolved a small portion of the starch, inducing a slight degree of setting, which will be known by the wort having a slimy feel; but Dr. Thomson observes that some obscurity hangs about the cause of the occasional cloudiness of the wort, which sometimes, with every precaution, will continue all through the brewing, and which cannot be removed ultimately but by fining. The wort, as it first flows from the mash tun, will be, in general, of a fine amber colour; but its tint will depend upon that of the malt, pale malts giving light-coloured worts, and brown malts giving darker coloured.

3094. *Upon the whole, the actual temperature of the mash cannot be absolutely fixed by any precautions*, which renders brewing more uncertain than could be wished, and demands some experience where great accuracy is required. But observations such as the above must form the basis upon which experience should be built.

3095. *The whole of the extract of the malt is not obtained by the process we have just described*, some of the wort already formed adhering to the malt, which will still contain a portion of undissolved extract, which requires to be farther acted upon by the warm water, as in the case of tea or other infusions.

3096. *These second and third additions of water to the malt are termed the second and third mashings.* It must be evident that the strength of the ale or beer will depend chiefly upon the proportions of the malt and water, but partly upon the management, as well as upon the sort of beer to be made. The particular mode of adjusting the proportions of the materials and other circumstances upon which the strength depends will be considered in the "*Practical Directions.*"

3097. *The first wort being drawn*, and put into the under-back, there are now several modes of proceeding, the choice of which will depend upon the kind of malt liquors required. If both ale and good table beer be wanted, the first wort alone may be reserved for the ale, as containing the most valuable extract of the malt, and the second and third mashings may produce the wort for the table beer, which is the usual practice; or these last two may be made into separate beers, the last being of very inferior quality. If it be required to make as much as possible of the best ale, then a certain quantity of wort may be still obtained from the malt of a quality nearly equal to the last, which may be added to it by the following process:

Pour, or, rather, sprinkle water, of the temperature of about 170°, on the surface of the malt in the mash tun, without stirring it, by means of a watering-pot having the holes in the nose larger than usual; or any kind of vessel, as a pail with holes in the bottom, may be suspended over the mash tun, and the water being poured into this, it may be moved about by hand and directed to every part of the mash. The tap hole of the mash tun being left open, wort nearly of the same richness as that at first obtained will flow, till the whole residue of the first wort which had been detained in the malt had run out. To know when to stop pouring on water, which should be done gradually, and at intervals, taste frequently the wort that runs out. When its sweetness diminishes greatly, which will take place almost suddenly, the tap hole is to be closed, and no more water is to be added. This wort is to be added to that already drawn. If any more water be added in the above manner, it will give a wort only fit for the table beer; its odour will be inclined to sourishness, although it be not, in fact, acid. This process is termed by the brewers *sparging*. But if it be required to make a good deal of weaker beer, as, for instance, table beer, then this last process may be omitted, and the second mashing gone on with immediately.

Before we proceed, it may be proper to mention that in the mash tun provision is made to prevent the malt which has been employed, now called *grains*, from coming off with the wort, either by a *strainer* in the inside, or by a double perforated bottom for this purpose, which will be described when we treat of the construction of the apparatus used in brewing.

3098. *Second mashing.*—There being still, as we have said, much of the extract remaining in the grains, warm water is again poured upon it in the mash tun, to make a second infusion. As there appears to be some difference of opinion with regard to the degree of temperature at which the water should be employed, it is necessary that we should resort to principles in determining this point. Richardson and other eminent brewers recommend that the heat of the water in the second mash should be 5° more than that of the first, and that of the third mash increased by 5° farther, raising the temperature in each succeeding mashing, in order to extract more from the malt. The reason for this is, in the first place, that all risk of setting is over after the first mash, and because it is desirable in the succeeding ones to obtain as much soluble matter as possible from the malt. But it has been observed by Dr. Thomson, Mr. Aikin, and other eminent chemists, that by far the greater part of the richest and most saccharine or fermentable part of the malt has been already extracted in the first mashing, which is reserved for the most delicately flavoured liquor; and that, although by this mode of proceeding, namely, increasing the heat in each mash, the second worts will acquire a greater specific gravity, yet that this gravity does not arise from saccharine matter only, but chiefly from starch and mucilage, substances which, when in excess, greatly deteriorate the quality of the liquor, and are liable to occasion failure by their turning acid. It is certain that the wort of the second mashing has but little sweetness, and a flavour and odour rather unpleasant than otherwise.

3099. *Third mash.*—The wort of the third mashing is of a greatly inferior quality, containing little else than mucilage, which, although by hopping may be made into a very indifferent small beer, is extremely apt to turn sour. Some, therefore, recommend that the water for the first mash should be 180°, that for the second 170°, and that for the third, if taken, 160°. With respect to the heat used in the first mashing, if it be too low, there is considerable risk of the wort contracting a sourness in the beginning of the brewing. In general, therefore, as Mr. Donovan admits, the higher heat is preferable. On these and similar subjects the judgment of the brewer must be exercised with reference to the object he has in view in brewing, and it is possible only to lay down principles for his guide.

3100. In great breweries, they sometimes make a fourth mash, but this is only used in what they call a *return*, which is merely used instead of water in the next brewing.

3101. *The whole of the kernel of the malt is never entirely dissolved by the hot water, even by the last mashing;* the husks, called *grains*, still contain a certain quantity, which is more or less according to the process, and form a nutritious food for cattle, pigs, &c. Grinding the malt finer would be favourable to a more complete extraction, but we have already stated the objection to this, from the difficulties of getting the water to pass through it in mashing without the aid of machinery.

3102. *The constituents of wort have been examined* by Dr. Thomson, Professor of Chemistry in Glasgow. By evaporating it to dryness, he found that it leaves behind it a yellow-coloured residuum, which has a sweet taste, dissolves readily in water, and becomes clammy, in appearance much like treacle; this cannot be procured in a perfectly dry state. He considers it to contain a good deal of the peculiar kind of sugar called starch sugar, which is similar to the sugar of the grape, less sweet than cane sugar, and which cannot be refined, though it may be granulated like granulated honey. Like the sugar of grapes, it ferments without the addition of yeast. We have already spoken of mucilage and starch also existing in the wort. The presence of mucilage with some gluten is shown by their being precipitated in flakes by the addition of alcohol or astringent matter. The mucilage is very apt to turn sour, though a certain portion of it is essential to fine ales. The existence of some unaltered starch is proved by a solution of iodine dropped into the wort producing a blue colour.

Subsect. 2.—*Boiling and Hopping.*

3103. *The next operation in brewing is to boil the sweet wort*, prepared as above described, with the hops. The wort or extract from malt may be compared to the must or expressed juice of the grape, both containing a considerable quantity of the same kind of sugar; and, in fact, it would be possible to procure a fermented liquor from the wort, either without addition, or only by adding yeast; but there are several important differences between the extract of malt and grape juice. Wort, besides being entirely deficient in the principle called *tartar* (which is found in the grape, and which will be mentioned when treating on wine), contains a much smaller quantity of saccharine matter, in proportion to the ferment. In consequence of this comparative abundance of the fermenting principle, if the wort were made to ferment at once, without boiling, as the juice of the grape does, it would very soon go through the vinous stage, and pass into the acetous, and, perhaps, the putrefactive; become *foxed*, as the brewers express it, and we should then, instead of beer, have only an ill-smelling vinegar, an effect which would be still farther increased by the large quantity of mucilage.

3104. *The chief use, therefore, of boiling the wort* is to get rid of some of this natural ferment, or gluten and mucilage, which are held in solution in too great quantity. This the boiling effects upon the principle of coagulation; for the gluten is coagulated or curdled by boiling water, in the same manner as white of eggs, and is thus easily separated from it. This coagulation, and likewise that of the mucilage, is farther assisted by the addition of the hops, which, containing an astringent principle, has a powerful property in coagulating these substances.

3105. *Another use in boiling the wort with hops* is to unite to the former the bitter and aromatic principles contained in the latter, which are necessary to cover the sweet mawkish taste of the sweet wort by itself, and give that agreeable flavour for which malt liquors are esteemed. It may, perhaps, be supposed that a decoction of hops might be added to the wort without boiling; but, as it is the boiling chiefly that effects the coagulation, this is necessary.

3106. *A third reason sometimes alleged* for boiling the wort is to evaporate part of the water, and thus render the wort stronger; but this is only in cases where too much water has been employed through error, or in consequence of bad calculation, which it is very desirable to avoid.

3107. *Wort, indeed, before fermentation, and after it, is extremely liable to acetify;* and this renders brewing an operation of great delicacy, slight circumstances being sufficient to mar its success, such as sudden changes of weather, or even thunder storms, to say nothing of the agency of witches, so much complained of in the olden time. The wort, therefore, should not remain long in the under-back, but should be transferred as quickly as possible into the copper to be boiled.

3108. *This coagulation, called breaking by the brewers, is generally accomplished* by boiling about half an hour, or nearly an hour, according to circumstances, and it is known to be sufficient by the appearance of flocculent masses swimming about and collecting in the copper; these gradually increase as the ebullition is continued, and they consist of the gluten and mucilage of the wort, which from the dissolved state have become solid by the combined operation of the boiling water and the astringent principle of the hops. When upon trial, by taking out a small quantity of the wort, it is found that the coagulation is complete, by the flaky masses subsiding to the bottom, and leaving the wort clear, the boiling is discontinued, and the wort is drawn off, in order to be cooled previously to fermentation.

As a proof of the utility of this operation of boiling, it is noticed that, if a quantity of wort be fermented without being boiled, the fermentation continues much longer than an equal quantity that has been boiled, and that the first will produce a thin liquor that soon becomes acidulous, and which is not calculated for keeping. Such liquors were probably made before the use of hops was known, and were required to be drunk very new.

3109. *The boiling must always be continued till this coagulation appears*, otherwise it will be useless, and a much longer continuance of it is injurious; about half an hour may be sufficient for extracting the soluble principles of the hop, but not always for the coagulation we have mentioned. If the boiling be continued too long, certain evils ensue; too large a quantity of the coagulable ferment may be separated, and the presence of some of this in the wort is essential to the fermentation, which then will be languid; the strength of the liquor will suffer, and perhaps the whole may acetify.

Another evil is occasioned by too long boiling, and also by violent boiling, which cannot be easily remedied, namely, the loss by volatilization of the essential oil of the hops, which contains the aroma. On this account, the hops should not be put in until the wort has boiled some time, that the rank flavour may not be extracted by too long decoction; and care should likewise be taken that the boiling should be as uniform as possible.

3110. *The greatest part of the flakes coagulated is detained* in straining the wort into the coolers; what remains is thrown out with the yeast in fermenting, and lastly, in the lees of the beer, thus freeing it from matters which otherwise would have remained in solution, or have rendered the liquor thick and turbid.

3111. *In some places a separate infusion of the hops has been made*, and afterward added to the wort, instead of boiling the hops with the wort; this has been recommended, as preserving the essential oil, which is sometimes lost in the common process, and as leaving out the rank flavour which long boiling extracts.

3112. *Among the improvements in brewing*, some of which might be adopted in domestic arrangements where expense is not an object, is boiling the wort by means of steam surrounding the outside of the boiler, instead of suffering the fire to come in contact with it; this will prevent all risk of burning the ingredients, and giving a disagreeable taste to the beer. The boiler that supplies the steam should be furnished with a safety valve, and the outside jacket or casing, between which and the copper the steam is introduced, may even be of wood.

Subsect. 3.—*Cooling the Wort.*

3113. *After the wort has been sufficiently boiled with the hops, it is necessary to cool it down to the proper temperature for fermentation;* and this must be done as quickly as possible, since the wort would be very apt to pass into the acetous fermentation were it kept long at a high temperature. The necessity of cooling the wort *rapidly*, though so important, is one of the most difficult and uncertain parts of brewing, as it requires that conveniences are had for exposing a very large surface to the air, and it is necessary, also, that the temperature of the atmosphere should be sufficiently low, on which account it is not possible to brew well in the summer, nor in a warm climate.

3114. *Cool dry weather is best adapted for brewing*, on account of the cooling of the wort; extremes of heat and cold are unfavourable, and therefore spring and autumn have been generally selected for private brewing. March and October are months well known as the fittest times of the year. In the great breweries they brew some beer in the summer as well as in the winter; but then they make use of large fans and refrigerators for cooling their worts, and even with these there is more risk than in cold weather; in winter, with a dry north or east wind, the cooling is speedily performed; but in frosty or very cold weather the fermentation is slow, except means are taken to keep up the heat.

3115. *In warm weather*, especially if at the same time the air is moist and close, the cooling is so far retarded that spontaneous decomposition of the liquor sometimes begins to take place; specks of white mould sometimes make their appearance on the surface, and communicate to the mass a rank and disagreeable musty flavour. In this state the liquor is said to be *foxed;* and the effect consists in an extremely minute species of vegetation growing in the wort, but which it would require a good microscope to recognise. Should this accident happen, it would be sure to increase in every subsequent stage of the brewing, and even during the consumption of the ale or beer.

3116. *To expedite the cooling* as much as possible, a variety of expedients are resorted to, which must vary according to the magnitude of the brewing, and the particular localities. In dry settled weather the wort is best cooled out of doors, but it must be carefully guarded from rain. When it is cooled within doors, all the doors and windows should be set open, and it is necessary to take care that the sun does not shine upon it. Thundery weather is particularly unfavourable.

3117. *The temperature to which the boiled wort is to be reduced previous to fermentation ought, if possible, to be about* 60°, or very little more. The injury, however, sustained by fermenting at too high a temperature is not by any means so great as the least de gree of foxiness; and therefore, if the weather be close and warm, and the brewer ha no other means of cooling his wort except by exposure to the air, let him ferment at 70°.

3118. In Scotland and on the Continent they ferment at very low temperatures; but Dr. Thomson observes that, when the room in which the fermentation is carried on is cold, if the wort is cooled down as low as the atmosphere, it often refuses to ferment, and artificial heat is obliged to be used before it will begin. He recommends that the temperature should never be less than 56°, except the room be warmer, in which case the temperature may even be reduced to 52°. The wort loses during the operation of cooling a considerable quantity of water by evaporation. The loss in the cooling is often more than one eighth of the whole bulk of the wort; its strength, therefore, becomes greater.

Subsect. 4.—*Fermentation of Malt Liquor in the Tun.*

3119. We now proceed to describe the principal process in brewing, that for which all that has hitherto been done is but preparatory. By this process the sweet mild decoction called wort is to be converted into a brisk lively liquor or *ale* containing a considerable portion of spirit. As the general principles of fermentation have been already fully treated of, we shall now only touch upon them as far as they are necessarily connected with our present subject.

3120. *We have said that a solution of perfectly pure sugar in water will not ferment of itself*, although one made with brown or coarse sugar ferments very readily. The sugar made from starch will likewise ferment of itself, and of course the saccharine matter of malt, as well as a solution of the sugar of grapes. In the general view of the fermentation of wort, therefore, we may suppose that the yeast employed might be omitted, because it is not absolutely necessary to this process, but seems merely to render the effect more certain and rapid, and consequently prevents the passage of the liquid into acidity, which almost always takes place when the fermentation is very slow.

3121. *In some of the counties in England it has always been a practice in private brewing to trust to spontaneous fermentation*, instead of employing yeast to begin the fermentation, as is the usual mode. Mr. Booth, who has seen this method, which appears not to be generally understood, informs us that when the wort is sufficiently boiled, it is put at once, boiling hot, into the casks, merely separating the hops without any clarification. In about forty-eight hours the fermentation is known to have commenced by the appearance of a froth or yeast which is seen to issue from the bung-hole. The quantity of yeast that comes out from the cask is not considerable, and in the course of eight or ten days the fermentation subsides. It is now found that the yeast, which has been forming all the while, has collected into a solid crust on the surface of the liquor, which has at last, in consequence of contraction as it cooled, shrunk away from the yeast, leaving a vacuity between the liquor and the crust; and it is said that this crust of solid yeast is of use in defending the beer from the air. This ale cleans by subsidence only, but requires to be kept for a twelvemonth before it is fit to drink. Only strong ale can be fermented in this manner, for weak worts would run into acidity before the vinous fermentation could be completed. A similar mode of fermentation is employed in Brussels and other parts of the Continent.

3122. *By far the most general method, however, in this country*, and which is considered as making the best and wholesomest malt liquor, is to commence the fermentation by adding to the wort a certain quantity of *yeast* procured from another brewing; and this is, accordingly, the method which we recommend, and which we shall now describe.

3123. *When the wort is cooled down to the proper temperature* by exposure in the coolers, which may be about 70° in temperate weather, according to some brewers, but with others as low as 60°, or even 50°, it is run into a strongly-hooped vessel, deep, and of a suitable size, called the *fermenting tun* or vat, or, as the brewers term it, the *gyle tun*. This should be larger than would be merely necessary to hold the wort, because a considerable increase of bulk takes place during the fermentation, in consequence of which the liquor would run over, except allowance were made for it. On this account its capacity should be one half greater than the bulk of the wort; and it should have a cover to exclude the air.

3124. *It may be proper here to recapitulate the leading facts which render this process of fermentation necessary.*

The vinous fermentation, or the production of alcohol or spirit, which forms the intoxicating part, or strength as it is called, of malt liquors, cannot be induced except through the medium of some kind of saccharine matter; and the use of malt is to supply a species of sugar, which, though not exactly the same as that of the sugar-cane, is yet equally fit for fermentation. A solution of coarse sugar in water, we have seen, will ferment of itself; but, to expedite this process, a substance called a *ferment* is added, which substance is contained in yeast that has been thrown up by some previous fermentation. When this ferment comes into contact with saccharine matter under favourable circumstances, a peculiar chemical action takes place, in consequence of which the sugar is decomposed or separated into its elementary constituents, and these are recombined in another manner, so as to give rise to two new substances, *alcohol* or *spirit*, and *carbonic acid*. The yeast itself is likewise decomposed; but the nature of this decomposition is obscure, and we may disregard it; since the alcohol and the carbonic acid themselves make up the exact weight of the sugar, we may consider it alone as supplying the alcohol. The alcohol being the liquid which we wish to form, it follows that the more sugar is decomposed the stronger will be the malt liquor; and its strength will depend partly upon the quantity of saccharine matter, or, in other words, malt or grain, employed, and partly upon the success with which the fermentation has been effected, the latter resulting, in a great measure, from the skill of the brewer. The carbonic acid gas or fixed air, separated by the fermentation, escapes through the liquor into the atmosphere, producing the appearance of ebullition, from which the process derives its name.

3125. *Having recapitulated these facts necessary to be kept in mind, we proceed to state* that, the wort being now in the fermenting tun, a certain quantity of yeast is to be added to it; and it is essential that this should be fresh and of the best quality, for bad yeast may spoil the whole brewing.

3126. *When wort is to be fermented for strong ale*, it is necessary to procure yeast from ale of equal strength. Though strong ales cannot be fermented by the yeast procured from weak worts, yet the yeast of ale will ferment any weaker beer. Weak beer ferments rapidly, but the fermentation is soon over.

3127. *Though yeast can be kept, yet new yeast is more active than old;* and it is a curious fact that, if successive brewings in the same place are inoculated with the yeast of the previous fermentations, the yeast will sometimes at last degenerate, in which case a supply must be had from another brewery. Yeast is also liable to become putrid by keeping, like animal matter; and the smallest quantity of this, or the least tendency to it, will inoculate the whole tun with its bad condition.

3128. *The best yeast* is that which is collected at the top, and which has become a dense tough froth, formed when the fermentation has been a good deal advanced. What has fallen to the bottom, or the *ground yeast*, is not so powerful.

3129. *The proportion of yeast that should be used* cannot be the same exactly for all cases, for it must depend partly upon the quality of the beer and on the season: in most cases, a larger quantity of yeast will have the same effect as a higher degree of heat in exciting the fermentation, and a smaller quantity will be equivalent to a lower temperature; but, in general, a gallon for four barrels may be stated as a general rule when the wort is from 60° to 70°; if the heat be greater, something less may be sufficient. If the fermentation is too languid, more yeast must be added to revive the action, without which the beer will not only be deficient in spirit, but have a mawkish taste compounded of sweet and bitter, be apt to fret on a change of air, and be peculiarly liable to turn sour. Great care must be taken to blend the yeast intimately with the wort.

3130. *The whole having been well mixed, and the cover put on the vat, fermentation commences* in from three to five hours, according to the temperature of the mass. A few bubbles may be seen first rising in the wort, and these collect first about the sides of the vat, where they soon form a kind of ring or line of froth: this gradually increases in breadth, advancing by degrees towards the centre, the liquor generally becoming turbid. At length the whole surface is covered by this frothy or cream-looking substance, which increases with a low hissing noise, owing to the breaking of the numerous air bubbles and the escape of the carbonic acid gas which they contain, the nature of which has been already explained.

3131. *As the fermentation increases in activity*, the froth or yeast rises higher, and is elevated partially in little pointed forms called *rocks* by the brewers. The yeast, at first white, becomes yellowish, then brownish yellow, or, rather, streaks and little masses of that colour collect upon it; these darker parts contain the bitter principle of the hop, and when it is not desirable that this shall be retained, as is the case in fine ales, the brewer skims it off that it may not mix with the liquor. About this stage of the process the brewer perceives a peculiar odour, somewhat of a vinous nature, called by the workmen by the strange name of *stomach;* and this continuing to acquire strength till the process is finished, the experienced brewer judges by it partly of the success of his operation. The froth at length becomes of a firmer consistence, being composed of a more viscid and glutinous matter, and the bubbles do not break so soon, but form larger than at first. The whole head, after this fermentation has continued some time, begins to grow flatter, the formation of froth lessens, and the dense viscid substance which had floated by its means would fall into the liquor if it was not skimmed off. This is done sooner or later, as the brewer wishes the fermentation to continue or to cease.

If he is desirous of continuing the fermentation, he will sometimes beat back the yeast into the liquor, and mix them together, which operation is termed *rousing*. If he wishes to check the fermentation, or considers it sufficient, he will carefully remove the yeast by skimming it off to preserve it for another brewing. As soon as the head of yeast ceases to rise the first fermentation is complete.

3132. *When the yeast is first added*, the wort is turbid, and has scarcely any degree of transparency; but as the fermentation advances, a gradual deposition of opaque matter takes place, and the liquor becomes comparatively transparent, as well as specifically lighter, in consequence of the spirit produced.

3133. *During the fermentation in the tub the temperature of the liquor continues to increase* till it be a few degrees warmer than when it was first put in, but the precise increase depends partly upon the temperature of the liquor at the beginning, partly upon the quantity of it, and partly upon the heat of the weather. In very large breweries it is said to rise even 12° or 15°, but perhaps not a third of this in private breweries.

3134. *Any sudden check to the fermentation is very injurious*, often occasioning a cloudiness in the beer which nothing can remove, and this same thing happens by a change in the weather; such alterations will affect small quantities much more than large ones, and, therefore, changes will be serious in small brewings that will not be much felt in those on a great scale.

3135. *A few farther remarks on the difficulties of this process or part of the art may be useful.* The smaller the quantity of wort to be fermented, the less is the heat excited by the process, and, consequently, the slower the fermentation. If the fermentation does not begin soon enough, or is too languid, the fault may lie with the yeast, which may be in too small quantity, or its quality may not be good, in which latter case it may be necessary to procure some from another brewery, though this is an evil that should, if possible, be avoided. If the quantity is too small, more may be added, from which little inconvenience can arise compared with that of an imperfect fermentation. Sometimes sifting a little flour of malt all over the surface is of use. Too languid a fermentation may also be owing to the temperature of the wort not being sufficiently high: in that case plunging a pail full of boiling water partly into the wort will raise its temperature.

If the quantity of yeast be too great, or the temperature of wort too high, the fermentation will go on too rapidly, and there will be danger of its passing into the acetous stage: when this is the case, everything should be done that will check the fermentation by cooling or otherwise. A pail of cold water plunged into the wort may be tried; the doors and windows may be thrown open. Too much yeast is liable to render the beer what is called *yeast bitter*. High-dried malt does not ferment so readily as pale malt, since the starch has become a little altered.

3136. *With respect to the extent to which the fermentation is to be carried*, this will depend upon the kind of liquor to be brewed: in ales it is not desirable that all the saccharine matter should be decomposed and converted into alcohol, because they require other qualities besides strength; it is requisite that they should have a certain degree of sweetness and viscosity; therefore the fermentation must be stopped before all these are destroyed. On the contrary, in porter, which may be called a dry malt liquor, sweetness is not wanted, and the fermentation is carried to a greater length.

Since alcohol or spirit is lighter, bulk for bulk, than water, it is evident that the more spirit there is produced by the fermentation, the lighter the wort which is fermenting will become; this lightness, which marks the quantity of alcohol produced, and, of course, that of the saccharine matter altered, is called by the brewers *attenuation*; and when they speak of the attenuation being carried far, they mean that the decomposition of the saccharine matter has been effected so much. The weight or specific gravity of wort is greater than that of water, just in proportion to the addition of the malt extract; hence the brewer has a mode of measuring this strength by means of an instrument called a *saccharometer*, and by the same instrument he can determine whether he has carried the fermentation as far as he ought, by ascertaining how much lighter it has become. This brings scientific brewing to a much greater degree of certainty than it could attain without the use of this instrument, which is now universally employed in this country by professed brewers.

But in private brewing a small difference in the strength of malt liquors is of less importance than in a manufactory, where a great part of the profits may turn upon it. Neither is it to be expected that this practice could be employed generally in domestic brewing; and therefore we have not introduced the description of the instrument.

3137. *Nothing positive can be said with respect to the length of time during which the fermentation of ale lasts*, because it varies considerably according to the heat of the weather, and the degree to which the wort has been cooled down. In ordinary domestic brewing it is generally completed in from twenty to twenty-four hours; but may sometimes require two or three days. In Scotland, in the great breweries, they ferment very slowly; for ten or twelve days, and even a fortnight or three weeks, which is considered by some as a good practice.

3138. *A small quantity of sugar is added to the malt* by some brewers when they consider the natural sugar of the malt not sufficient. This proves sometimes a useful addition, and serves to increase the strength of the liquor without the risk of running into the acetic state.

SUBSECT. 5.—*Cleansing and Barrelling.*

3139. *When the fermentation appears to have, in a great measure, subsided*, by not throwing up any more yeast, it will still go on for some time, but in a much more quiet and less obvious manner, a few bubbles of gas rising occasionally. The liquor cannot become quite clear so long as this is the case, since loose particles of the dregs, or subsided yeast, will continue to float about. There is still some fermentable matter remaining in the liquid; and the continuance of a languid fermentation would soon cause the ale to run into acidity if the wort were suffered to remain in the vat; the yeast which had risen to the surface would subside to the bottom, where part of it would be dissolved by the spirit of the beer, and it would communicate an unpleasant bitter, which is termed by the brewers *yeast bitter*.

3140. *A second fermentation is therefore necessary*, to get rid of the remaining fermentable matter; and this process is performed in casks or barrels, into which the new malt liquor is now transferred from the fermenting tun. This second slow fermentation is by the brewers termed *cleansing*, because the beer seems to be cleansed of much foul matter, which consists chiefly of mucilage and exhausted ferment, part of which subsides to the bottom, under the name of *dregs* or *lees*.

3141. *As the yeast works out of the casks*, it leaves, of course, a vacancy, which must be filled up daily by beer reserved from the fermenting tun; and when the discharge of froth has ceased, or nearly so, which will be in about a week, more or less, the bungs are to be put in, and well secured. A slight fermentation continues for some days in the closed cask; when this has ceased, the feculencies begin to subside, leaving the liquor quite bright and clear.

3142. Transferring liquor from one vessel to another, termed by the brewers *racking*, always forms a considerable check to fermentation, by getting rid of the sediment, or lees, which contains a great deal of the ferment. In this case, if the quantity of the liquor in the fermenting vat be so considerable as to fill several barrels, it is evident that the temperature will be reduced by its being divided into portions; and in cold weather this check is sometimes too considerable, since it is necessary that the fermentation shall still go on slowly in the barrels. When this is the case, brewers, a little before racking, *rouse* or stir up the yeast and wort, to revive the expiring fermentation, or even add a little yeast.

3143. *If all the previous processes have been well managed, the beer itself will absorb all the carbonic acid gas that is generated in the enclosed cask*, which will be retained by the drink from the mechanical pressure to which it is subjected; and this will constitute that appearance of briskness which beer should have when just drawn, a property owing to the sudden disengagement of the gas which has been pent up in the liquor. While remaining in this state, the barrels should occasionally be examined by opening the vent-peg a little, lest the gas should collect in too great a quantity, when the barrels might burst, an accident which has been known to happen.

3144. *In a few months ale is generally fit for use*, though some is kept for a whole year before it is drunk; and it continues to improve all that time, provided it has strength or body enough, and it is kept sufficiently cool to prevent its passing into the acetous fermentation. The slow fermentation is some security against this, since any change can be more easily watched.

3145. *It is essential that a certain portion of the saccharine matter shall remain unfermented*, that, by its slow fermentation while keeping, the liquor may be *fed*, as it is called; that is, supplied with slow and gradual additions of alcohol and of carbonic acid, to prevent that flatness and heaviness which would ensue from the loss of the latter principle. Should it happen that the beer appears to ferment too much after being barrelled, another racking may be found necessary. By repeated rackings the fermentative matter may be got rid of, and such beer at last become clear and transparent; it may, if bottled, remain for years without *coming up*, as it is technically called. The object of the brewer should be to produce an agreeable beverage, distinguished not so much for absolute strength, or quantity of alcohol, as for colour, flavour, transparency, liveliness, and power of keeping for a long time.

3146. *It is essential that the casks shall be kept well closed*, to prevent the escape of the fixed air that is formed, and the access of common air. We have stated that the slow fermentation in the casks is useful in forming continual small quantities of carbonic acid gas, and, as this is absorbed by the beer, the latter is always saturated with it; likewise, what little vacant space there may happen to be in the cask above the beer will be completely filled with the gas, even a little condensed, which will prevent more from being liberated, or even formed, because there is no space for it to expand in, on which account the slow vinous fermentation is long kept up, and so long as this does exist in any degree, the acetous cannot begin; but when the surface of the liquor is exposed to the common air, the carbonic acid flies off as soon as it is formed, and room is thus given for the formation of more; what remains, therefore, of the vinous fermentation to take place is soon finished, and then the acetous will begin; in other words, the liquor will turn sour. This effect may be easily perceived when a cask is tapped; for the beer, brisk at first, after a time gets flat, from the want of carbonic acid, and, if it is not all used quickly enough, what remains sours.

Bottling, the most perfect mode of preserving malt liquors, is, in fact, like putting the liquor into very small casks, where all the effects are exactly similar to those just described. See farther, on this subject, under "Bottling Beer," Sect. X.

Sect. IV.—PRACTICAL DIRECTIONS FOR BREWING.

3147. *Having now given a general view of those scientific principles upon which the art of brewing should be conducted*, we proceed to lay down such plain practical directions as are necessary to be attended to. We have already pointed out how much brewing requires the knowledge of its theory; but it would be difficult, perhaps impossible, to draw from the mere theory of an art the best modes of practice, since these have been the result of long experience, not by one only, but by various persons. The following practical directions have been drawn from the best sources; but we have already stated that no rules can be laid down that can serve as infallible guides in all cases; and hence we would recommend the attentive perusal of the previous section. But as there may be many persons who may wish to brew their own beer, without having leisure or inclination to pay so much attention to the theory as may be required, we have endeavoured to render this section as complete a guide as possible by itself.

Subsect. 1.—*Explanation of Technical Terms.*

3148. *In every trade there are some terms peculiar to it*, consisting of the names of parts of the apparatus used, or of particular operations. These terms, called *technical*, are frequently unintelligible to those not belonging to the trade, and throw a sort of mystery over the whole practice. This, which is, perhaps, in some degree unavoidable, impedes considerably the diffusion of knowledge by creating a kind of *cant* language, which is sometimes resorted to for the purpose of concealing the processes.

3149. *It is very desirable that these terms, often very unmeaning, should be employed as little as possible*; but in the mean time we propose to translate the brewer's into the ordinary language, or, in other words, to give an explanation of their technical expressions.

Liquor.—This is always the brewer's term for water—a word which he never uses.

Pale malt.—Malt which has been exposed to slight heat only in the kiln.

Amber malt.—Malt which has been exposed to a degree of heat somewhat greater.

Brown malt.—Malt which has been dried so much as to change the colour of the grain a little.

Patent malt.—Malt that has been roasted like coffee.

Slack-dried malt.—Malt which has been dried in the kiln less than usual.

Grist.—Malt that has been ground for mashing.

Goods.—The brewer's term for the ground malt in the mash-tub.

Mellowed malt.—That which has been exposed to the air for some time, and which, consequently, has imbibed some water hygrometrically, in contra-distinction to that which is fresh from the kiln.

Backs are large vessels of any kind intended to hold wort. The term is probably a corruption of the French *baque*, which signifies the same thing.

Liquor back.—The water cistern to supply the brewery.

Liquor copper.—Copper for heating water.

Wort copper.—Copper for boiling the wort and hops.

Mash tun, or *tub.*—Vessel for infusing the malt.

Mashing oars.—Sticks for stirring up the mash.

Mashing machines are used in great breweries for stirring the mash.

Tap-tree.—A wooden shaft for stopping the hole in the bottom of the mash-tub.

Setting tap.—Letting off the sweet wort.

Under back.—Vessel to receive the wort when let off from the mash-tub.

Hop back.—The first vessel for the wort to cool in, where the wort is drained from the hops. This is also sometimes called the *Jack back.*

Coolers.—Vessels to cool the wort in.

Gyle tun, the *fermenting tun*, or *fermenting tub.*—The vessel in which the fermentation is carried on. This is also called the *working tun*, and by the great brewers *squares*, from their form.

Pitching the wort.—Setting the wort to ferment; applied particularly to the degree of heat; as pitching at 75°.

Working.—Fermenting.

Stomach.—A strange cant term used by the workmen for the spirituous odour perceived in fermentation.

Sparging.—Sprinkling hot water on the grains, to obtain more wort after the first has been taken.

Stillions.—Vessels to receive the yeast that drains from the barrels; this name is also applied to the supports of the barrels.

Store vats.—Large vessels for keeping malt liquor to supply customers from.

Entire gyles.—When there is only one kind of beer from the same malt.

Party gyles.—A name used by the excise for making two kinds of beer from one malt.

A gyle of beer.—The whole quantity made at one brewing.

Blinked.—A species of acetification to which beer is liable.

Foxed.—When specks of white mould form in the wort as it is cooling.

Yeast-bitter.—When too much yeast has been used, and the beer is rendered too bitter.

Racking.—Transferring beer from one cask to another, to get rid of the lees or sediment.

Lengths.—A term used by the brewer to express the whole quantity of one kind of wort made from a certain quantity of malt.

Making up lengths.—Making up the whole quantity of beer of a certain strength.

Coming up.—Beginning to ferment again.

Cleansing.—The second, or slow fermentation that beer undergoes in barrels before it is finally put into the casks.

Rounds.—Large vessels like hogsheads, in which brewers transfer the porter from the fermenting vats, to undergo the slow fermentation previous to its being put into the store vats.

Attenuation is the conversion of the sugar of the malt into spirit, and the consequent reduction of the specific gravity of the fluid in the fermenting tub from this change.

Briskness of ale or beer is that state in which there is a quantity of carbonic acid compressed in it, which flies off when exposed to the air.

Flatness is the want of the last quality.

Heaviness seems to be the same thing, but with more alcohol.

Fretting means a slight fermentation, by which the beer becomes again turbid.

Feeding the beer is managing so that there shall be some saccharine left to cause a slight fermentation, which gives an addition of alcohol and carbonic acid.

Rousing.—Stirring up the beer so as to excite the fermentation.

Heat at which the tun is pitched.—The temperature at which the fermentation is begun.

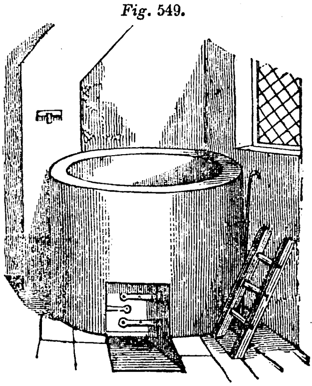
Return.—Water which has been put to the grains after all the wort has been run off, to be used for another brewing instead of water alone.

Subsect. 2.—*Description of the Vessels and Instruments used in Brewing.*

3150. There are certain vessels required in every brewery; but the exact kind will depend partly upon the opulence of those who brew, and partly upon the scale on which the operations are to be carried on. When economy is not so much an object as to have everything very complete, considerable ingenuity may be employed in fitting up the brewhouse, for which many hints may be obtained from the practice of professional brewers. In smaller establishments more simple apparatus will be found sufficient, and in many cases it may be an important consideration to reduce these to the greatest simplicity possible, and to show with how little expense and trouble brewing may be effected. The several modes have their particular advantages, and every individual must choose the style of the various implements which best suit his circumstances and convenience. In our description of the apparatus, we shall include the cheapest as well as the most complete kinds for private brewing.

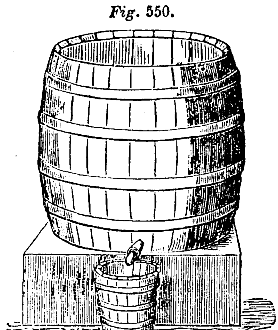
3151. *Copper.*—The water is heated in a copper fixed for the purpose, if the brewing be on a tolerable scale, or in a portable one if the brewing be very small; in short, the size of the copper must depend upon the extent of the establishment, and what is required. *Fig.* 549 is a copper set of the smallest kind. In the best arranged breweries, the copper and reservoir of water are placed at the upper part of the building, for the convenience of the liquids descending lower and lower, from one stage of the process to another, thus avoiding the labour of raising them up. But this great convenience, the advantage of which will be easily comprehended in following the various parts of the brewing processes, cannot always be obtained; and the mode of arranging the vessels must depend very much upon the situation. There is sometimes considerable difficulty in preventing the contents of the copper from burning, which, if it should happen, will give a disagreeable taste to the beer; an improvement has been employed in great breweries, of boiling by means of steam, which obviates this inconvenience.

Fig. 549.



3152. *The mash tub,* or *tun.*—This is the vessel which is to hold all the ground malt, or grist, and water enough to make the infusion of sweet wort for ale. It should be large enough to hold the whole of the wort of which the ale is made, and all the malt; there should likewise be room enough besides to mash in, which requires at least five or six inches in depth, that is, the liquor should not reach above five to six inches from the edge of the mash-tub. It is generally made of wooden staves fixed by hoops of iron or wood, *fig.* 550, or a porter barrel may be sawn in two to make this and the fermenting tub. All that is essentially necessary is to have a tub or other vessel capacious enough to hold the malt and water to be infused, with a contrivance at the bottom to let off the infusion, or sweet wort, into another vessel. For this purpose some have a cock fixed near the bottom; but in cheaper apparatus a spigot and faucet, *a b, fig.* 551, is found sufficient for those who cannot afford the other. This, in the common one, is merely driven tight into the hole in the lower part of the tun, and the peg takes out; but this simple contrivance has several defects which a cock is free from: the wood is apt to swell with the hot liquid, and then can scarcely be moved; also, in attempting to draw off the wort it will sometimes issue suddenly and scald the operator. An improvement is to have a screw cut upon the faucet, as at *d.* Sometimes, to keep back the grains, a basket, *e,* is placed within the mash-tub, into which the spigot and faucet is driven.

Fig. 550.



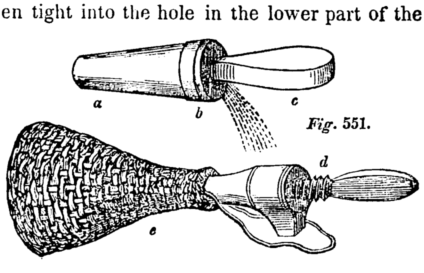


Fig. 551.

3153. *A simple and old method for the same purpose, used in many farmhouses,* is the following: In the middle of the bottom of the mash-tub, *a, fig.* 552, there is a conical hole, *b,* about two inches wide across, to draw the wort off through. Into this hole goes a stick called the *tap-tree, c,* a foot or two longer than the tub is high, and about two inches thick, and tapered for about eight inches upward at the end that goes into the hole, which at last it fills up as closely as a cork. Upon the hole, before anything else is put into the tub lay a little bundle of fine birch or heath, *d* (straw *may* do), about half the bulk of a birch broom, and well tied at both ends. This being laid over the hole, to keep back the grains as the wort goes out, put the

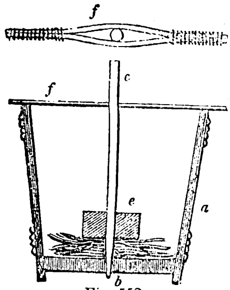

Fig. 552.

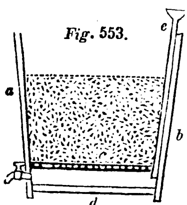
tapered end of the stick through the birch into the hole, and thus cork it up. To prevent the birch rising with the stick when you lift it up to let off the wort, a weight, *c*, must be placed upon the birch, and this is best done by making a leaden collar or ring, weighing three or four pounds, to slip over the stick, and slide down upon the birch. Some make shift with the iron box of a cart-wheel; but any contrivance will do that will prevent the birch from rising. To keep the stick at any height you may require, as you are drawing off the wort, the following method may be employed: Take a rod or branch of ash, hazel, or almost any wood; let it be a foot or two longer than your mashing-tub is wide over the top; split it down the middle, as for making hoops; tie it with a string at each end; lay it across the mashing-tub; pull it open in the middle, and let the upper part of the wort-stick come *through* it, as is represented at *f*. Now, when you raise that stick to let the wort off, let the split stick close upon it, and by its spring it will hold it up any height you wish; but this, though an old contrivance, is one which would scarcely be used if a spigot and faucet, with a wicker basket, which only cost eighteen pence, can be got; still, it is useful to know every resource. From this apparatus, brewers still term letting off the wort *setting tap*.

3154. Some recommend for a mash tun a vessel made in the following manner: A wooden vessel, *a b*, *fig.* 553, is provided with a double bottom, the uppermost one being pierced with holes. A pipe or trough, *e*, goes down from the top to the space between the two bottoms. The grist being put into the mash tun, water of the proper heat is poured into the pipe, and it descends into the space between *c* and *d*, and then ascends, by hydrostatic pressure, through the holes in the uppermost bottom, *c*, and, coming into contact with the grist, floats it, as the latter, when dry, is specifically lighter than water. In no great length of time the water begins to be absorbed by the malt, which then falls down. The use of the two bottoms is, that the wort may pass down into the space between them, and be drawn off clear, and the water is introduced below the malt, instead of the top, to avoid pressing the malt into the holes of the double bottom, and thus choking them up. The mashing tun is, in general, a little wider at top than at the bottom, though some prefer the contrary, that is, widest at the bottom, to prevent the grist from being compressed: it need not be quite so deep as it is wide across. The holes in the false bottom, if in wood, should be burned with a hot iron, and not bored, and should be a little conical, that is, wider below than above. The diameter of the holes at the upper part should not be above an eighth of an inch.

Fig. 553.



3155. As it is sometimes the case that a quantity of the grains of malt will get through the holes in the false bottom, which are difficult to get out, except this bottom be loose, some prefer the following contrivance: Four pieces of wood bored full of holes are nailed together in the form of an obtuse wedge, *fig.* 554, and this is placed over the hole by which the mash is drawn off. This simple apparatus stops the grains from passing out as effectually as a double bottom, and as it is merely put down loose, the difficulty just mentioned is obviated. It is necessary to state that this perforated wood must be fixed by a hook and eye, bolt, or some such contrivance, to prevent its floating. Its size must be proportioned to the quantity of the mash.

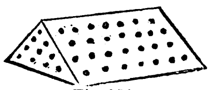


Fig. 554.

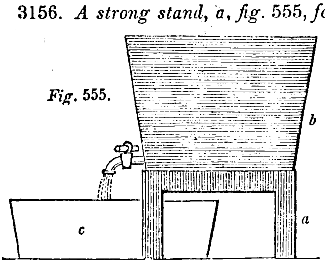
3156. *A strong stand, a, fig.* 555, *for the mash tun, b,* if large, is necessary: two stools may do for a small brewing. The stand should be high enough to admit of a tub standing under the mashing tun to receive the wort; but it should not be too high, or it will increase the labour of lifting up the water.

Fig. 555.



3157. *A shallow tub, called an under-back, c, fig.* 555, is placed below the mashing tun for the wort to run off into when drawn from the grains. Its size is proportioned to that of the mashing tun. It is best to be large enough to hold all the wort of one mashing, that the wort may not be cooled by being transferred into other vessels previous to boiling. But some make shift with it of smaller size, and collect the wort into the fermenting vat, until it can be boiled. In small brewings a good sized washing-tub will do very well.

3158. *A mash stirrer, fig.* 556, is a stick rather larger and stronger than a broomstick, with two or three small pieces of wood, eight or ten inches long, put through the lower end of it and sticking out on each side. Three or four sticks, of the size of broomsticks, may be also useful occasionally in stirring.

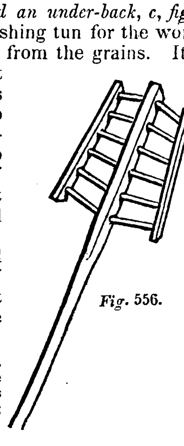


Fig. 556.

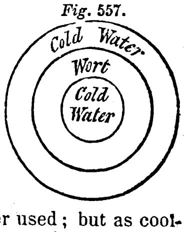
The size of the mash-tub must depend in some degree upon the mode of brewing. If one kind of beer be intended to be made at three mashes, for every firkin, or nine gallons of beer, the mash-tub should contain fifteen gallons. Thus, if two firkins of either ale or table beer be required, then the mash-tub must hold thirty gallons; and if one firkin of ale and two of table beer be wanted, the mash-tub must be of the same size. But if the brewing is proposed to be done with only two mashings, employing a larger quantity of water in the second mash, then the capacity of the mash-tub must be eighteen gallons. From these data, any one desirous of brewing may easily fix upon the size of the mash-tub when they have determined upon the quantity they intend to brew at one time. This and all the other vessels may be furnished by the cooper.

3159. An economical mode of procuring vessels for a small brewing is the following: One of the largest sized casks sold at the wine merchants may be procured; then cut off the two ends about a foot deep, which will serve for coolers; and a bottom may be put to the middle piece to serve as a mashing tub, or a porter barrel may be sawn in two to make a mashing tub and fermenting tub. It is important that the heat should be prevented from escaping from the mash-tun, and it should therefore be kept covered with thick woollen cloths, or some lid of a non-conducting kind.

3160. *Coolers* are flat tubs, trays, or other vessels for the purpose of cooling the wort before it is fermented. In small brewings, common washing-tubs will do tolerably well. Since the quicker this operation is performed the better, there ought to be sufficient provision made of these before the brewing commences, that as much surface may be obtained as possible: the fermenting tun may serve for one.

3161. In considerable breweries the coolers consist of shallow cisterns made of boards well jointed, with sides raised about ten inches all round; and the wort is put into these only about two inches in depth; several of these are placed at some distance above each other; often in the upper part of the building the sides are constructed with boards placed in the manner of a Venetian blind, so that the air has a free passage through the building. In some cases, where there is a great command of water, they make the wort traverse a pipe bent or twisted in form of a distiller's worm, or in any other convenient mode, which is placed in a cistern of cold water. In one brewery they have long used an apparatus consisting of three concentric cylinders, *fig.* 557; a stream of cold water, pumped up from a well, passes through the inner one, and also between the two outer ones; the intermediate cylinder conveys the wort, which, being every way surrounded by cold water, is soon cooled without being exposed to the air.

Fig. 557.



In domestic brewing such ingenious methods are seldom or never used; but as cooling the wort is often a matter of considerable difficulty where the space is limited, it is a proper subject for the exercise of invention. The ordinary method is to get together all the large shallow tubs or other vessels that are at hand; but in private brewhouses of a superior kind shallow fixed cisterns are used.

3162. *Care should be taken that the coolers, and, indeed, all the vessels employed in brewing, are perfectly clean,* as the least acidity or mouldiness remaining from a former brewing is almost sure to inoculate the wort and spoil the beer. To ensure this, merely washing them with hot water is not always sufficient, particularly if they have lain by without being used for any length of time. It will then be necessary to employ some substance that will neutralize and destroy any acid matter that may remain, such as potash, soda, or lime.

3163. *The fermenting or working tun,* or *vat,* in which the ale is fermented or worked, the brewers often call the *gyle tun.* In a complete brewhouse, this is a large tub kept on purpose. In brewing on a small scale, any tub will do that is clean, strong, and large enough to hold ale, and have room to spare for the head of yeast. A cask deprived of its head may sometimes serve as a fermenting tun for the ale, and the small beer may be fermented in the mash-tub.

In brewing on a great scale, it is supposed that the loss of a certain quantity of alcohol which escapes with the carbonic acid during the fermentation is an object worth attending to, and contrivances have been invented for fermenting in closed vessels to prevent it, and even for preserving the alcohol that would be lost. We may just mention that the fact of the evaporation of the alcohol is proved by hanging grapes in the gas as it escaped from the fermenting tun, by which they acquired the taste of alcohol as if they had been preserved in brandy; and it has been demonstrated that closed vessels afforded worts somewhat stronger than open ones; but, in private brewing, this loss from fermenting in open vessels must be so inconsiderable, that it cannot be worth while to do anything more than to cover the fermenting tub with cloths.

3164. *A hair sieve,* or *a wicker basket,* through which to strain the beer from the hops, must be provided.

3165. *A light pail or two* should be kept for brewing only, that they may be perfectly clean; also a wooden bowl with a handle, to carry liquor from one vessel to another.

3166. *A tun bowl,* or *large funnel,* through which to put the liquor into the barrels, is necessary.

3167. *The casks for containing the beer* must be of a size suitable to that of the family. The longer the beer is to be kept the larger the casks should be, as it thus acquires strength; but where a family is small the casks ought not to be large, as they would be so long in tap that the beer would become flat. Casks or barrels holding eighteen gallons are most convenient in general. Each cask must be well fitted with a bung, vent-peg, &c. These casks should be kept very clean, and, though they may be cleaned by good rinsing if not very foul, the only perfect mode is by taking out the heads, so that they can be well scoured with a birch broom to remove a slimy matter which forms, and which rinsing alone will not remove. This is generally done by the cooper, but any one may soon learn to do it.

The iron hoops of casks should be kept painted, to preserve them from rusting. Immediately after they are empty, the vent-peg should be fastened down, and the tap-hole stopped with a cork well fitted and hammered in, to prevent the access of air, which would soon cause the mouldiness to grow, and spoil the beer, not only of one brewing, but probably of several successive ones.

3168. *Thermometer.*—This instrument is found of great service to the brewer, and should always be employed where accuracy is required. It will be found particularly useful to those who have not had much experience in brewing, and who are unacquainted with many signs and symptoms which the practised brewer avails himself of. By it the proper heat of the mash is regulated, and of the worts when drawn from the mash tun. It points out when the worts in the coolers are of the proper temperature to begin the fermentation; and it marks the progress of this process by the increase or diminution of the heat. For this purpose there are thermometers of great length, to allow of their going through the head of yeast into the wort, while the necessary part of the scale is above the froth.

Subsect. 3.—*Construction of the Brewhouse.*

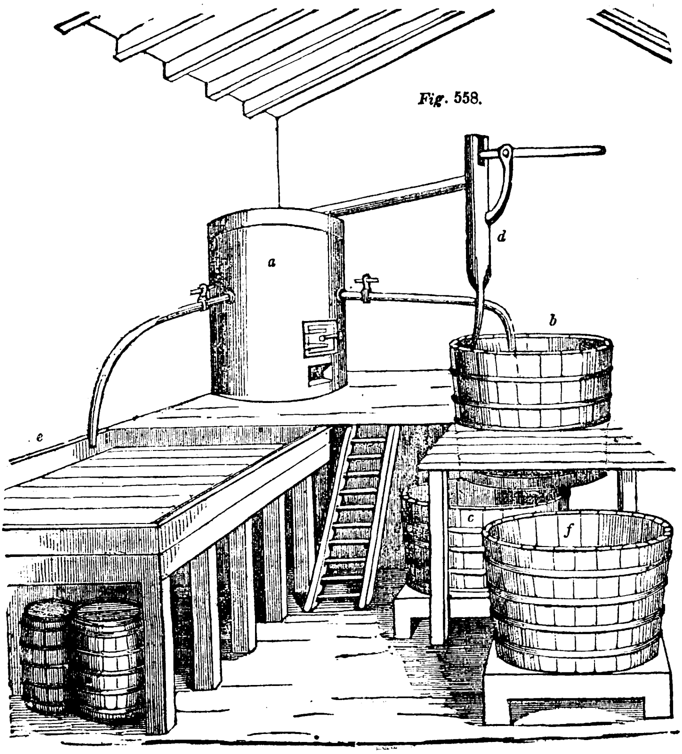
3169. *In small establishments,* if brewing is performed at home, the washhouse is frequently also the brewhouse; but, where it can be afforded, it is much better to have the brewhouse a separate building.

3170. *The complete mode of arranging a brewhouse* is to have all the parts so disposed that the liquor should not be carried from one place to another; but it should flow through pipes by descent in the various stages of the processes, so as to occasion as little trouble as possible. With this view, the water cistern should be in the highest part of the building, and below should be the copper; then, in a descending order, the other vessels, until at last the beer runs into the casks in the cellar. Beer may be conveyed to any distance by leathern pipes with screw joints.

3171. *The situation for the brewhouse* should be airy, and detached from the house. There should be a plentiful supply of water, soft if possible. It is desirable to separate the place for boiling and mashing from that for cooling and fermenting, to prevent the heat of the boiling from affecting the cooling. A yard is best for cooling, or an open shed. The mash tun and under-back are best above ground; it is a bad way to have the latter sunk below. The coolers should be large, and should communicate with each other. Fans or refrigerants are useful for driving off the steam and cooling the wort: this will also protect it from foxiness, which stillness is apt to promote. The fermenting tun should be insulated, and not touch the wall or ground.

3172. *In the great breweries,* the various apparatus for brewing are ingeniously contrived, and disposed in a very convenient manner for operations on a great scale; but, few of these being applicable to domestic brewing, we omit entering into any description of them as foreign to the object of this work; recommending, however, a visit to one of these establishments by those who are desirous of acquiring an enlarged and comprehensive idea of this manufacture.

Fig. 558.



3173. *The arrangement of a private brewery* is not unfrequently as in *fig.* 558. *a* is the copper, supplied with water from a cistern above; *b* is the mash tun, served with water from the copper by a pipe; *c* is the under-back, from which the sweet wort is pumped up by the pipe *d* into the copper, to be boiled with hops: from thence it is run into the cooler *e*, which, when the brewery is considerable, is made of boards, and is raised upon strong supports. When of the proper temperature, the wort is sent into the fermenting tun, *f*, by means of a temporary trough placed from the cooler. After the fermentation is over, the beer is drawn off into casks or barrels, and put into the cellar.

Subsect. 4.—*On purchasing the Materials for Brewing, and the Quantities required.*

3174. The general nature of the several materials necessary for brewing malt liquor, namely, malt, hops, yeast, and water, have been already described. A few words may be useful on the mode of procuring them.

3175. *Malt.*—As much of the quality of the beer must depend upon that of the malt, the safest plan is to go to a respectable dealer, on whose judgment and integrity confidence can be placed.

For the character of good malt we refer the reader to what has been said on the subject in Section V. It is best to buy it unground, and to grind it at home, as then it will be certain not to be adulterated. It is cheapest in the end to purchase the best malt; for, setting aside the risk of having the brewing fail through bad materials, the quality of the beer will be of more consequence than any saving in the malt.

3176. *The quantity of malt* must, of course, be proportioned to the strength of the beer required to be made. The average strength is such that a bushel of malt will give twelve gallons; and this may be taken as the most useful proportion in general, and the one generally employed in domestic brewing, for common ale not intended for long keeping.

Brewers reckon that one measure of ordinary ale is equal to two of table beer; therefore, from one bushel of malt may be brewed twenty-four gallons of table beer, supposing no ale to be made; or nine gallons of ale, and six of table beer, or six gallons of ale, and twelve of table beer, or any other proportion of these two kinds of beer, so that half the number expressing the table beer added to that expressing the ale shall make twelve gallons.

In private families, strong ale is sometimes made, as much as a bushel and a half to twelve gallons. If ale be intended for long keeping, it will be requisite to allow more than a bushel of malt to twelve gallons. If weaker ale be thought sufficient, less malt, perhaps three quarters of a bushel, may do. Taking these proportions as standards, every one may choose that proportion which best suits his taste and his means. In private brewing the table beer is generally made from the malt after the ale has been extracted from it.

3177. *It is to be understood that the malt is to be measured before it is ground,* because a bushel of malt produces, when coarsely ground, one bushel and a quarter of *grist*, and when ground fine the increase of bulk is more considerable. If the malt be purchased in a ground state, allowance must be made accordingly.

3178. *Hops.*—The same observations which were made on malt will also apply to this ingredient. The best is the cheapest.

3179. *With respect to the quantity of hops,* this must depend upon several circumstances: upon the kind of malt liquor to be made, the quality of the hops, the length of time the beer is to be kept, and partly upon the season of the year when it is brewed. One pound of hops to a bushel of malt is the usual proportion for ale that is to be kept; that is the proportion used in the Edinburgh ale. The stronger the ale, the more hops it will bear, and if the ale is to be kept long, it may require a little more. Much here must depend upon the taste of those who drink the liquor. In England it is the custom to use rather more hops than in Scotland: Edinburgh ales have the least. For weak ales, a pound of hops to a bushel and a half of malt may be used, or ten ounces of hops to a bushel of malt; and this may do if the ale or beer is intended for present use, and is not to be kept long. Ale brewed in warm weather may require from a pound to a pound and a quarter of hops to a bushel of malt; in cool weather, three quarters of a pound will generally do. It seems to be the fashion at present to have beer for the table much hopped, and very bitter; for this, of course, the proportion of hops must be increased.

3180. *Hops vary much in price,* according to the kind, the season, and the abundance of the crops. Hops may be grown by private individuals; but before picking, drying, &c., a duty to the excise must be paid of 1¾*d.* per pound; the using of unexcised hops renders any one liable to a penalty of 50*l.*

Subsect. 5.—*Particular Detail of the Process of Brewing.*

3181. Method and regularity is of great importance in conducting every kind of business, but is particularly so in brewing; for as the principal operations are begun and finished within the course of a short period, any neglect or hinderance is very likely to be the cause of marring, if not of spoiling entirely, the whole.

3182. *Before beginning to brew, everything necessary should be properly prepared*, and a great deal should be done on the day before the actual brewing commences: the materials should be quite at hand; the various vessels be in a proper state to be used, and should be placed in proper order; the copper should be filled, and the coals provided for the fire.

3183. *On the day for brewing*, the copper fire is to be lighted early in the morning, and while the water is heating, tubs may be filled with cold water ready to pour into the copper for the second mash. When the water boils, it is to be poured into the mash-tub, and the copper should be filled again. The nature of mashing has been fully described, Sect. III., Subsect 1; and the quantity of water employed in the several mashes must depend upon the proposed strength of the several kinds of beer to be made; but in the *first* mash, an allowance must be made for the quantity of water which the malt will absorb and retain, and so much must be poured upon the malt, over and above that of the wort required, to make up for this. Well-made malt absorbs and retains water in the proportion of six gallons for every bushel of malt; therefore, whatever be the required quantity of the first wort, water more than this, in the proportion just mentioned, must be made use of. Besides this water absorbed by the malt, something will be lost by evaporation in boiling, cooling, and fermenting, the whole of which together will amount to about one fifth of the quantity of beer required to be made. Suppose, for instance, that fifty-four gallons of beer were required to be made from four bushels of malt, then twenty-four gallons of water will be absorbed, and eleven gallons more must be allowed for waste; that is, twenty-four and eleven, or thirty-five gallons extra of water must be used above the fifty-four gallons. This quantity of water may be divided between the two mashes, according to the strength required for each.

3184. *The best method of ascertaining the proper temperature is by using a thermometer;* the heat of the water should depend in some degree upon the nature of the malt, and likewise upon various circumstances which have been already explained under the head "Principles of Brewing," Sect. III.; and it is impossible to fix upon any absolute degree of heat that should be constantly employed, different brewers varying in their practice several degrees from each other. 170° by the thermometer is that which is most generally recommended for the heat of the first mash, when pale malt for ale is to be brewed. Some brewers use a higher degree of heat, 175°, or even 180°.

3185. *When a thermometer is not to be had*, or where persons are not in the habit of using it (although this is very easily learned), the method employed by some to ascertain the right heat of the water is as follows; and, although this mode is far from being accurate, yet it is much better than none: Put the water into the mash-tub nearly boiling, and wait till the steam has gone so much off that you can see your face clearly in the water, or else draw your finger quickly through the water; and if you can do so without scalding it, the heat is right. It is very obvious that neither of these methods can be very exact; but much good ale and beer has been brewed in this manner by those who have had experience. Beginners should use a thermometer.

3186. *Another method may assist in getting a proper heat:* Mix two gallons of boiling water with one gallon of cold water, that is, water of the heat it is usually of in moderate weather, the mixture will be about 170° of the thermometer. It must be observed that 170° is the heat that the water is required to be of when the malt is added; but as the water will be cooled a little by the mash-tun, it may be run in a few degrees above this, to allow for cooling down to that point.

3187. *It is best not to put the full quantity of water into the mash-tub at first*, but only so much as will serve to wet the malt or grist thoroughly, and make a thick mash. The malt should be shaken in quickly, and a second person should stir it about well with the mashing oar or stick described above. The malt must be thoroughly broken and mixed, so that there are no clots or lumps, on the same principle as in making paste.

In this state the mash may remain for a few minutes, and, in the mean time, having got ready more water of the proper heat, the mash-tub should be filled up to the proper height by adding the remainder of the water by degrees, according to the quantity of the ale intended to be made, stirring all the while, and mixing the whole well with the oars for twenty minutes or half an hour, according to the quantity of the malt. Some sticks should then be laid over the mash-tub, which should be covered with cloths, sacks, blankets, or old carpets, to keep in the heat, and the whole suffered to remain quiet for about an hour and a half.

3188. *When it has remained so as long as is considered necessary*, the sweet or ale wort should be drawn off. For this purpose, the cock or spigot should be opened, a very little at first, to see if the wort runs clear. This must be done with caution, letting the wort run with a small stream, lest some of the grains or floury matter should come with the wort. The first gallon or so that is drawn should not be suffered to go into the under-back, but should be put into a bucket, and if it is not quite clear, it should be returned gently into the mashing-tub, and a little more time allowed, till, by several trials, the wort is found to come clear: the cock or spigot may then be opened, and the whole run off into the under-back. If the heat of the liquor has been managed judiciously, with respect to the quality of the malt, the wort will run perfectly clear. If it does not part freely from the malt, the heat has been much too high, and the malt has been subject, more or less, to the accident of *setting*, which is carefully to be avoided, since this is irremediable, and the brewing runs great risk of being totally spoiled The wort should be about the temperature of from 140° to 150° when it runs into the under-back. While the wort has been mashing and running off, as much water must be boiled in the copper as is sufficient for the second mash, scalding the casks, &c.

As the ale wort is drawn off into the under-back, it should be laded into the fermenting tub, by means of the bowl with a handle, to be ready for the boiling, if the under-back is not large enough to hold the whole of the wort; but if there is a second copper, it should be transferred into it immediately, which is the best practice.

The water that has been heating in the copper is now to be poured upon the grains for the second mash, for table beer. But to prevent confusion in our account, we will leave the second mash for the present, and follow up the process of managing the wort that is to be made into ale, and when we have got that into the cellar, we will then return to the second mash and the preparation of the table beer.

3189. *The next process in brewing, after making the first mash, is boiling the sweet or ale wort with hops.* In our "Principles of Brewing," we have shown that the chief use of the hops is to coagulate the mucilage of the wort, and to communicate an agreeable aromatic bitter to the liquor.

If there is only one copper, as soon as it has been emptied of the water that was boiled in it for the mash, the fire should be damped to prevent burning the copper, and a little water should be left in the boiler to cover the bottom.

The ale wort is next to be put into the copper, and with it the proper quantity of hops, well rubbed, and separated, or previously steeped in water; and great attention must be paid to the boiling, to prevent the liquor boiling up suddenly. The hops must be kept down with the mash stirrer, and be well broken, and at last they will subside to the bottom; but care must be taken lest the latter should stick to the bottom of the copper, which would cause them to burn to, and infallibly occasion an unpleasant taste.

No certain rules can be given for the time the boiling is to continue before the coagulation may be expected, as that will depend upon the strength of the wort, and of the hops. Strong worts will generally require from half an hour to three quarters, and weaker ones from two hours to two hours and a half. The coagulation, called *breaking*, is observed first by the liquor becoming clouded with large fleecy flakes which appear swimming about in it. When the boiling has continued for some time, it is necessary to take out a small quantity of the wort from time to time in a convenient vessel (a large glass is best); the liquor will at first appear foul and turbid, from the flakes or curdy substances. A great part of this, being heavier than the wort, will subside. When no more subsidence takes place, and the wort is clear, it is a proof that it is sufficiently boiled; and there is no advantage in continuing the boiling longer, except the wort be found too weak, and it is thought necessary to evaporate some of the water, a circumstance which it is desirable should not be necessary, since that will dissipate the aroma and fine flavour of the hop; and, indeed, this is seldom required, except when a mistake in the quantity of the water is to be rectified.

3190. *When the time for boiling has expired,* the wort must be carried to the coolers. But first it must be strained from the hops. In large breweries this is done by passing the wort into a vessel with a perforated bottom, called the *hop-back;* on a small scale, a portable strainer or wicker basket will do.

3191. *The coolers ought to be in sufficient number,* and may be placed within doors or without, in the open air, as may be convenient; a couple of sticks may be laid across one of the coolers, and the basket put upon them; then the liquor, hops and all, may be put into the basket, which will keep back the hops; the liquor should be of the same depth in all the coolers, otherwise the wort would cool unequally.

It is most convenient to have the coolers below the level of the copper, that the wort may run into them by a pipe, or an open shoot; but, if it is not convenient to have the coolers low enough, the wort may be pumped up into them, or may be carried to them in pails.

3192. *The quicker the wort is cooled the better,* which makes it very difficult to brew in warm weather; and it is very important to cool down exactly to a certain degree, since much of the success of the fermentation or working will depend upon the heat of the wort when it is put into the fermenting tun. The heat usually cooled down to is 70°, which is best ascertained by a thermometer; but those who brew without this instrument determine the heat by putting the finger into the wort. It should feel just warm, *gently lukewarm*, or as milk just drawn from the cow. It may be well to observe that the liquor will cool a little in removing it into the fermenting tun. If the wort be cooled too slowly, it is apt to contract *foxiness*, a mouldiness appearing upon the surface that gives a bad taste to the beer, which, in warm weather, is very liable, in this stage of the process, to turn sour.

3193. *When the wort is sufficiently cooled, it is put into the fermenting tun,* and now is the time to add the yeast, to excite the fermentation.

3194. *The quantity of good solid yeast to be used* should be proportioned, not only to that of the wort, but also to the heat of the weather, and of the fermenting liquor (see "Principles of Brewing"). One quart of good, stiff, fresh yeast may be used for forty gallons of good strong beer or ale wort; and one pint and a half to the same number of gallons of small beer wort. In larger or smaller quantities, the yeast may be in proportion. If the weather be cold, rather more than the quantity just mentioned may be applied; and in hot weather it will be prudent to diminish the quantity, lest the fermentation should be too rapid. If the heat of the fermentation be about 70°, one pound and a half, or one pound and three quarters of yeast per barrel may be sufficient. If the heat be about 60°, then two pounds, or two pounds and a half of yeast will be required, the quantity being increased with the lowness of the heat. The danger is the least of employing a little too much yeast; imperfect fermentation is worse. It is of great importance to have the yeast good and fresh; if it be at all tainted, it will ruin the whole brewing.

3195. *It is a good practice to set the yeast to ferment, a little before it is wanted,* in a bowl or pail, by adding to it a portion of lukewarm wort, and stirring them together, putting in more wort as the fermentation proceeds. When this mixture is decidedly in a state of fermentation, it is to be poured into the liquid to be fermented, and incorporated well with it by stirring.

3196. *The degree of heat in the wort at the time the yeast is put in* is very important to be attended to. This may be from 60° to 65° or 70° in temperate weather; but the exact degree must depend partly upon circumstances; and as the heat of the fermentation will increase after a little time, allowance must be made for this. In general, in the small way, it is safest not to have the heat too low; about 65° may be a good medium heat.

It is desirable that the place where the fermentation is carried on should be of the right temperature; if the air should be about 55° it will be proper; any cool place in summer, and any warmish place in winter. If the weather be very cold, it will be useful to surround the fermenting tub with sacks or other cloths, or to have a fire in the room. This is the more necessary, as small quantities do not maintain their heat so well as large; and one of the chief difficulties in a small brewery is the keeping up a proper heat in the fermenting tub while the fermentation is going on. When the yeast and the wort have been properly mixed together, sticks must be laid across the fermenting tub, and sacks or thick cloths laid over it, and then it must be left for some time.

3197. *The fermentation having fairly commenced is denoted* by the appearance of very small air bubbles, which in a few hours will increase and put on the appearance described in Chap. III., Sect. III., Subsect. 4. This is one of the most critical periods in brewing, and the fermentation requires very constant attention. The frothy head of yeast will keep rising more or less slowly for about forty-eight hours; but the length of time for the working cannot be precisely fixed, as it varies with circumstances. When the head of yeast has risen considerably, and assumed a uniform appearance, it will begin to sink, and then it is proper to skim it off. This skimming should be repeated every few hours, otherwise, if brownish curdy matter, which is now seen upon the yeast, and which is the intense bitter of the hop, is suffered to fall back into the beer, it will give a bitterness and rankness of flavour which the brewers call *yeast-bitter*, and it will be difficult to get the beer bright at last. The yeast collected by skimming should be put into a larger vessel than is necessary to hold it at first, as it will swell a little; it will contain a quantity of beer, which will separate from it by suffering the mixture to stand for a day or two; this beer may be added to what has been fermented, and the yeast may be kept for another brewing, and for baking.

It has been stated that the heat of the fermentation regularly increases while it is going on; at first very slowly, but at last more rapidly before it declines. While the heat continues to increase, which can be ascertained by the thermometer, we may be certain that the vinous fermentation is not over; but when the heat no longer increases, the fermentation is probably complete, and then the smell of the ale may be perceived. When the fermentation is at its height, on holding the nose below the edge of the fermenting tub, the fixed air disengaged will strike extremely sharp, so as to sting the nostrils; but at the close of the fermentation the strength of the gas diminishes considerably, so as to feel only just warm in the nostrils. The ale will then be found to have acquired its proper taste and smell; the head of yeast will be uniform and compact; and there should be no sweet taste. Should the fermentation not go on so well as could be wished, the reader must refer to the article "Fermentation," Sect. III., under "Principles of Brewing," with a view to discover the cause and the remedy.

3198. *It is an essential point to know the precise time when the fermentation has been carried far enough,* but no general rule can be given that will apply in all instances; it must vary according to circumstances, and here experience is necessary. Attention is to be paid to the head of yeast. This, when the fermentation is brisk, begins to turn speedily of a brown colour and compact consistence, so that it would fall back into the beer; at that period the fermentation is nearly complete. If the beer is intended to be what is called *hard*, the fermentation must be continued the longer; but if the beer is wanted to be *brisk*, the fermentation is stopped the sooner.

3199. Particulars of this kind steadily kept in view, with a little practice, and ordinary powers of observation, will enable any one to brew; but, after all the directions that can be given, a certain degree of practice with skilful persons is necessary.

3200. *Some allow the fermentation to go on a little longer than others;* but it must not be completed in the fermenting tun, otherwise the beer would soon be quite flat and sour. When it sends up very few air bubbles, but before it has quite ceased working, the liquor, now beer, is to be transferred into casks where the fermentation is finished. The fermenting tub may be uncovered for an hour or two before the beer is transferred to the casks, or *tunnel*, as it is called. The beer may be run off by the cock, when the yeast will remain behind; or the yeast may be removed from the top with a large flat skimmer or ladle with holes. Great care should be taken that none of the yeast finds its way into the casks, which would endanger a fresh fermentation more considerable than is required.

3201. *The fermentation is now to be completed by the slow process* in casks, called by the brewers *cleansing*, when a great deal of yeast and sediment works out of the casks that otherwise would prevent the beer from keeping. The casks or barrels, which are supposed to have been perfectly well cleaned, are placed upon low stands about a foot high, called *stillions*, with their bungs leaning a little on one side. They are filled from the fermenting tub by means of a funnel; and in general the beer is suffered to be quite cold before this is done. The casks are placed in the cellar, into which the beer may be brought down in buckets, or sent down by a pipe, and they may be kept leaning on their stands by means of wedges or pieces of brick, so that the wort that works out may run into pans placed below. It is essential to the cleansing, that the casks should be kept always quite full, otherwise the yeast will not run off, and then the beer will not be transparent. To effect this, every day, as the yeast works out, they are filled up again by some beer which was reserved for this purpose from the fermenting vat. When the casks are filled up, a few strokes with a mallet on the hoops will cause some bubbles of air to escape, and leave room for a little more beer to be added.

This cleansing of the beer may take a week or a fortnight; and what beer has run out, after being separated from the yeast, may be returned into the cask again. The pans placed to receive the yeast should be cleaned daily. If the beer works briskly, the filling up of the casks should be done every two or three hours at least for the first ten or fifteen hours; after that term, the slow fermentation will probably, in some degree, subside, and they need not be filled up so often.

3202. *When this second fermentation is over, and no more yeast works out, the casks must be righted*, or placed with their bung-holes at top, and secured in this situation by blocks. If the fermentation, instead of being as slow as is proper, is too considerable, it is sometimes found necessary to rack off the ale into other casks; but this is not favourable to its preservation.

3203. *The casks are now to be bunged up close.* A bit of linen is put round the bung, and it is hammered in tight; the vent pegs are also to be put in, but they should be opened occasionally for a few minutes to allow the gas to escape; for though a certain portion of this is essential to the briskness of the beer, yet too much will prevent its fining. The beer now remaining still, the impurities will subside, and if the brewing has been properly performed, nothing more is necessary, and the ale or beer will become clear in about fourteen days without any other attention. Some persons recommend putting a handful of hops into each cask with the beer before it is bunged down; and it is said that they will communicate their fine aromatic flavour more than those that are boiled with the wort. There is, however, some danger by this practice that the hops may stop up the cock, except some precaution is taken to prevent it. The best method probably is to suspend them in some sort of netting.

3204. *It is not advisable to bung up the casks before this slow fermentation is quite finished;* for, if this be done, the beer is liable to fret and turn sour. So long as there is a head of yeast in the bung-hole there is no danger of the beer becoming flat, since the carbonic acid gas in the cask will effectually keep out the common air. To ascertain when this second fermentation is quite over, and the cask ready to be bunged up, clear away with the finger all the yeast inside the cask round the bung-hole as far as can be reached, and then lay a piece of thick brown paper over the bung-hole, and press it down, so that it adheres by means of the clammy yeast. Look at this in a few days, and if the paper is burst, or is wet, it is a proof that some air has yet to be disengaged, and that the fermentation is not quite over. When this does not happen, the beer is ready. As to the length of time the ale or beer is to be kept before it is to be used, that must depend, in a great measure, upon taste.

3205. *Mode of proceeding with the second mash, or the brewing of the table beer.*—In describing the operation of mashing, we stated that, as soon as the water of the first heating in the copper was poured upon the first mash, more water was put to boil for the second mash to make the table beer. The quantity of this water will, of course, depend upon that of the beer to be brewed. The heat of the water is made about 5° greater than that of the first mash, in order to extract as much soluble matter as possible, the risk of *setting* being now, in a great measure, over. This mash must be stirred with the oars for about half an hour, and it should stand an hour and a half. A sample of the wort should then be taken; the wort is then suffered to run out till it cease, or nearly so. As soon as the copper is empty again (the ale wort that was in it having been put into the coolers), the small-beer wort is to be put into the copper with the hops from which the ale wort has been drained, and some persons here add a little fresh hops; this liquor is now to be boiled for an hour. In the mean time the mash-tub should have been cleared of the grains, and the basket may be placed on some sticks laid across the mash-tub; the small-beer wort from the copper should be poured into it through the basket. When sufficiently cool, it must be set to ferment in the same manner as ale, but using a larger proportion of yeast; this should be in the proportion of three half pints to thirty-six gallons of small beer. The rest of the management of the table beer is the same as that of the ale, only it should be put into the casks a little warm, otherwise it will not work in them as it ought to do. The table beer will not ferment so strongly as the ale, nor so long, and may be put into the cask much sooner—in general, the next day after it is brewed, and it will be ready to tap in a few days.

3206. *Mixing the worts of different mashes.*—If one kind of malt liquor only be wanted, the different mashes, whether two or three, are mixed together, and the strength of the mixture determines that of the malt liquor. If more than one degree of strength be required, then the produce of the several mashes are kept separate for each sort, or they may be mixed so as to proportion the strengths in any manner that may be desired. The usual practice in private families is to make the ale from the first mash, and the small beer from the second, or, perhaps, the first and second mashes are made into ale, and the third into small beer; or the first into strong ale, the second into table ale, and the third into small beer. In large breweries, the mixing of worts to make up a desired strength is a matter of nice calculation, in which the saccharometer is of essential use.

3207. *If there were as many coppers as mashes,* the wort from each mash could be boiled in a separate copper as soon as it was made, and kept at the proper temperature till they could be mixed; but when there is only one copper, as is usually the case in the small way, the produce of the first mash is obliged to be kept for some time in the under-back, or some other vessel, because the copper is employed in heating water for the second mash; and although this vessel is covered up and kept as warm as possible, yet there is a risk of the sweet wort remaining so long as to lose much of its heat, and, in consequence, of its beginning to change by a slight kind of acetification, which will be very injurious to the beer, and it is then said to be *blinked.* Two coppers would obviously prevent this accident. Blinking is also produced sometimes by the mash being suffered to remain so long as to cool too much before it is drawn off, or by the heat not being sufficiently high at first. To regulate all this exactly, a thermometer is extremely useful. To keep up the heat in the under-back, where the wort remains for some time, a worm with steam might be made to pass through it, the condensation of the steam supplying heat to the wort. A common tea-kettle, properly fitted up, would furnish steam sufficient for this purpose.

3208. *On taking a review of the processes just described,* and the multiplicity of circumstances to be attended to, it is easy to see that brewing is an operation that requires considerable skill and dexterity to manage it with complete success. The goodness of the beer will depend upon the quality of the malt and hops; on the degree of heat and length of time employed in mashing; on the mode of boiling the wort; on the proper management of the fermentation; on the precaution used in tunning, &c.; in short, every part of the process requires nice attention to the proper manner of performing it to prevent failure. Many of the difficulties can only be overcome completely by practice and personal experience; but these, as we have observed, may be considerably diminished by attention to rules drawn from the experience of others, and by studying the theoretical principles of the art: the knowledge thus acquired constitutes what is denoted by the term *skill.*

3209. *Professional brewers always keep a journal,* in which they enter regularly every circumstance respecting each brewing, such as the quantities, temperature of the water in each mash, and fermentation, all changes observed, &c. This is a very useful practice, since it not only prevents many errors, but serves as a record of the various parts of the process. Such a book would be equally useful in domestic brewing, and is much better than trusting all this to memory. Each brewing may be considered as a set of experiments, which, when registered, assist materially when the process is to be performed again. The young brewer should anxiously watch each operation, carefully mark its success or failure, and should apply to the various appearances he may observe those scientific principles which he has learned, and not whimsical and unfounded reasoning

SUBSECT. 6.—*Receipts for Domestic Brewing.*

3210. *The following are receipts by which domestic brewing has been successfully performed on a small scale,* and which will help to illustrate certain variations in the methods employed by different persons:

3211. *To brew three bushels of malt into ale alone.*—This quantity of malt will make thirty-six gallons of ale. Procure a cask that will hold thirty-six gallons or a little more, and put as many pails as will equal that quantity into the copper to boil. When brought to a proper heat, put half of it on the malt in the mash-tub, and let it remain the proper time, having covered up the tub. When the mash has remained about three hours, run the wort off. Put the rest of the warmed water on the mash to extract a second quantity of wort; let this remain an hour, and run off the wort. Add some more water to allow for what has been lost by evaporation, and what has been absorbed by the malt, to make up the quantity of thirty-six gallons. Mix the worts together; boil the usual time, and add the hops. When the wort has boiled sufficiently, cool, and, having added a quart of yeast, put the whole into the fermenting vat. The time of fermenting must depend upon the weather and other circumstances. When the fermentation is over, put the ale into the cask for slow fermentation; when this is finished, the cask must be bunged.

3212. *To make ale and table beer from four bushels of malt.*—The first mash will make the ale, and the second and third the table beer; these are to be fermented separately. To the mash for table beer ten pounds of sugar may be added. The ale may be boiled with four pounds of hops, or more if it be preferred rather bitter, and to be fermented the usual time according to circumstances. The table beer is to be treated in the same manner. After this they should be put into casks to cleanse, which will probably require fourteen hours or more. About two pints of yeast will be sufficient for the whole of the fermentation. When the cleansing is over, the casks are to be bunged.

3213. *To make ale and weak table beer from two bushels of malt.*—Choose pale malt. Add about twenty gallons of water sufficiently warmed to the malt in the mash-tub. Stir well, and let the whole remain quiet for an hour. Run off the wort clear; and it is to be observed that the quantity of wort will not equal the quantity of water poured on the mash, much being retained by the malt. Make a second mash by adding fifteen gallons more of water. Mix the two mashes together for the ale, and add twenty gallons of water for a third mash for the beer. The ale will require three pounds of hops to be boiled with it for twenty minutes or half an hour. The wort is then to be put into coolers, cooled down to 96°, and then fermented by a quart of yeast. When the fermentation is finished, cleanse as before; about twenty gallons of good ale will be obtained. The wort for the table beer must be treated similarly.

3214. *One bushel and a half of malt is a convenient small brewing,* and it will give eighteen gallons of ale, and also some table beer. Much smaller quantities may be brewed, and some have recommended even four or five gallons; but the trouble is the same, and the larger quantity will keep best. For this purpose a copper will be required that holds at least twenty-two gallons, and a mash-tub that will hold about twenty-eight gallons; also, three nine-gallon casks will be required. When two of these are empty, a fresh brewing may be begun. The expense of such a brewing has been calculated thus:

	£	s.	d.
Copper and setting - - - - - - - -	2	10	0
Mash-tub - - - - - - - - - -	0	14	0
Two pails - - - - - - - - - -	0	6	0
Sieve - - - - - - - - - - -	0	2	6
Bowl - - - - - - - - - - -	0	1	6
Spigot, &c. - - - - - - - - - -	0	1	0
Three nine-gallon casks - - - - - -	0	18	0
	4	13	0

The mode of proceeding is so exactly the same as we have described that we need not repeat it, and the quantities of water, hops, &c., may be in proportion.

3215. *Brewing on a still smaller scale may be effected*, such as was commonly performed by the agricultural labourers before the present duty was laid on malt. A nine-gallon cask of beer may be easily brewed with very few utensils, all of which will not cost more than forty shillings; a portable boiler, a mashing tub that answers also for a fermenting tub, and a shallow tub or two for coolers. If the boiler is portable, the whole of the brewing may be done out of doors.

Sect. V.—Of various ingredients sometimes added to malt liquors, chiefly for the purpose of adulteration.

3216. *Malt, hops, and water are the only materials permitted by the legislature to be used in manufacturing malt liquor for sale;* and this strict enactment was made on account of a practice which had formerly prevailed of their employing various other ingredients, some of which were destructive to health. At present the introduction of any other substances than those named above is *illegal*, whether harmless or highly deleterious. The public brewer is thus restricted from experimenting on various improvements that might be made; nevertheless, the regulation is salutary; since, were there no other reason, the ignorance of some brewers and retailers of the properties of the substances they might use, would no doubt occasion our beverages to be converted frequently into poisons.

3217. *From common report, it is generally supposed* that malt liquors which are retailed are sometimes *adulterated* by various illegal ingredients; but whether introduced surreptitiously by brewers or publicans, it is impossible to determine. On the truth of this opinion we do not pretend to decide, and we believe that many brewers as well as retailers are too conscientious to be guilty of such practices. Some substances prohibited are, in small quantities, useful in correcting defects in the liquors, and are innocuous; others, again, if introduced at all, are so with fraudulent views, to save the expense of the proper materials or for other objects, and are exceedingly detrimental; most of the latter are of an intoxicating quality, and injurious to the human constitution; these are of such a nature that, unfortunately, they can scarcely be detected even by the chemist, who has often no means of distinguishing them, when put into malt liquor, from what belongs to the hop. The bare possibility of such practices furnishes a strong argument in favour of individuals brewing their own ale and beer, by which alone they can ensure a wholesome beverage. To such a height had the evil arisen, before it became a subject of parliamentary investigation, that the providing various articles for the purpose of adulterating beer had become a distinct trade, under the title of *brewers' druggist.* At present, we had hoped this race had become extinct, but we are informed that it is still a common practice for certain persons to travel through the country to dispose of *drugs* to brewers and publicans. This prohibition of certain articles, however, does not extend to those who brew for their own consumption only, and not for sale; these are at liberty to employ any materials they choose. It is very proper, therefore, to understand the nature of the various substances which have been, and which still are, probably, employed on occasion, both to put persons on their guard and to destroy prejudices. Such of these prohibited substances as are harmless may become very proper subjects of experiment with the domestic brewer, who may be desirous of making an improved beverage.

3218. *We may divide these ingredients* into, 1, those which were employed to communicate a bitter or other desirable taste to beer, in order to qualify the natural sweetness of the malt; 2, those which were added for the purpose of increasing the intoxicating properties of the liquor; 3, those intended to correct acidity; 4, those used in fining; 5, substances used for colouring.

3219. *It was a very ancient practice to infuse, in beverages fermented from grain, certain bitter and aromatic herbs*, partly for their flavour, and partly from their supposed medicinal properties; and thus we read of *spiced* and *herb* ales. Many of these materials were of a bitter nature, which was found useful to correct the luscious sweetness of the malt, and such were found also, in general, to make the liquor keep longer. Hence it has been generally supposed that this preserving property was owing to the bitter principle; this, however, as we have already observed, does not appear to be evident.

3220. *The bitter of plants is not uniformly the same kind of substance:* all plants do not contain the *astringent* principle which coagulates the mucilage of wort, which is the part most liable to become sour. Such vegetables as possess both the bitter and astringent principles are peculiarly fitted for making beer; but none of them are found to be superior, or even equal to the hop. Some of them, however, are tolerable substitutes, and are employed in various places.

The common box (*Buxus sempervirens*) is much used in all the beer brewed in Paris at the present time, as has been lately stated by M. du Petit Thouars in a communication to the Philomatic Society. Box-wood contains a powerful sudorific principle, with a bitter taste, which has lately been separated, and is known by the name of Buxiana (*Bull. Univ.*). In some parts of France, as well as in Germany, the top of the *common broom* is employed; and this, as well as *heath*, has been used from time immemorial in Norway, Sweden, and the north of Scotland. All these possess the astringent principle. In England, *mugwort* and *wormwood*, though less proper as preservatives, being chiefly bitters only, have been used formerly. It is said that the foreign bitter, quassia, and likewise gentian, are employed at present in the porter breweries.

Quassia is the wood of a plant that grows in the West Indies, and the decoction is much used in medicine as a useful tonic. The active principle is intensely bitter, and is called *quassina*.

Gentian is the root of the *Gentianea lutea*, a plant which grows very abundantly in the Alps, Pyrenees, and Apennines. The bitter extracted from them is intense, and proves an excellent tonic, being found particularly applicable in such diseases as require the combination of bitters and chalybeates, as in cases of direct debility. It is in no way poisonous, but it contains a saccharine principle which causes it to ferment rapidly and spoil; therefore it does not contribute to the preservation of beer, though it gives it bitterness; and it is a mistake to suppose that it is a good substitute for hops.

Calamus aromaticus is a plant of a spicy, bitter taste, formerly used in aromatic tinctures for medicinal purposes, and which has been employed to supersede hops; it grows in this country, and is collected for the use of brewers and distillers.

Wormwood and *horehound* are likewise used, it is said, to diminish the quantity of hops.

Catechu, absurdly called Terra Japonica, has been used with success by some brewers for the purpose of more effectually precipitating mucilaginous matter in beer, which it does from containing a powerfully bitter and astringent principle. It is an innocent substance, employed in medicine as a tonic, and is an extract prepared in India from a plant called Acacia Catechu; it is there chewed with the betel nut.

Aloes are said to have also been used; but they are very improper, being powerfully cathartic.

3221. *But the most objectionable of the substances used in adulterating malt liquors* are those narcotics intended to increase their intoxicating quality. These are all pernicious, and the following list is truly frightful; it is to be hoped that they are now seldom employed:

Nux vomica is the fruit of a tree called *Strychnus Nux Vomica*, which grows in the Indian Archipelago. The seeds, which contain the active principle, are extremely bitter. They contain a considerable quantity of *strychnia*, the most deadly known poison except Prussic acid. Strychnia is so intense a bitter that one grain of it dissolved in eighty pounds of water produces a bitter solution. A sixth part of a grain is sufficient to kill a dog.

St. Ignatius's bean, or *bitter bean*, is the seed of an East Indian plant (*Strychnus St. Ignatii*). It contains 19 parts in 1000 of strychnia.

Cocculus Indicus is the berry of the *Menispermum cocculus*; it contains a bitter, intoxicating substance, called *picrotoxine*, and so violent a poison that ten grains will kill a dog in a very short time. A great deal is brought from India; and no other use is known for it except in the adulteration of beer. It is certain that this has been employed in porter from evidence given before a committee of the House of Commons.

Grains of Paradise is another similar substance, said to be largely employed for the same purpose.

Opium is a substance, the narcotic qualities of which are well known; it appears in the list of intoxicating ingredients.

Tobacco is said to be used in beer in some way, from its narcotic or other properties. It is very injurious when taken into the stomach.

Bohemian rosemary and *henbane* are two poisonous substances, said also to be used.

Some other substances are said to be employed by brewers occasionally, to give some particular flavours or to correct defects, as *ginger*, *coriander seed*, *caraway seeds*, &c.

By the use of these narcotics, weak malt liquor has been made to imitate strong porter, constituting a beverage extremely improper. It is true that a very small quantity of any of these poisons may be taken internally without danger, and are even employed in medicine; they should, however, be confined to the materia medica, and only used under the direction of a skilful physician, but by no means mingled with our common drink; and there is little doubt but that the stupifying effect of some malt liquors is owing to their adulteration with some of these deleterious ingredients. Unfortunately, too, very few of these poisonous vegetable drugs can be detected by the chemist, and are only recognised by the stupifying and injurious effects which they produce. Mineral adulterations can be detected, such as copperas, sulphuric acid, lime, soda, potash, &c.

That great quantities of these deleterious ingredients are imported, we learn from official returns, from which it appears that in one year there were brought into the kingdom no less than 154,864 lbs. of cocculus indicus, 140 tons of quassia, 218,624 lbs. of gentian root and nux vomica.

3222. *Various materials employed to correct the acidity* of beer and other liquors will be described when treating on the management of the beer cellar, Sect. VIII. These are all alkalies and alkaline earths, and are in themselves harmless, as *carbonate of soda*, *chalk*, *whiting*, *egg shells*, *pounded oyster shells*, and *marble dust*.

3223. *Substances used for fining* are described in Sect. IX., "Fining;" they are, *isinglass*, *white of eggs*, and *hartshorn shavings*.

3224. *For colouring*, only *burned* or *roasted malt* is allowed to be used by the brewer: this has been already described under "Malt."

Burned sugar was employed by the brewers formerly, and may still be in domestic brewing. There are two modes of preparing it. One is to burn the sugar in an iron vessel till it becomes a thick sirup, perfectly black and extremely bitter. The other method is to boil the sugar to a middle state between sweet and bitter. To both these preparations it is necessary to add lime-water before they are suffered to cool in the pot, in order to bring them to a proper temper, as without this they would become hard, dry, burned substances; but no water must be put to them before they are sufficiently burned. *Liquorice* is probably also used for its colour.

3225. *Beer heading.*—Among the adulterations of porter ought to be reckoned what is thus termed. One of the qualities of good porter is, that it should bear a fine, frothy head, since professed judges of this beverage would not consider it as perfect without this requisite, although it might possess all the other properties of good porter. Genuine porter, fresh drawn, when poured from one vessel to another, exhibits on its surface a close, creamy foam or head, which, when blown aside, instantly closes again; but if the porter is too weak, perhaps from an adulteration with small beer, this head is deficient. Some publicans have endeavoured to conceal this poverty by laying on the surface of the beer, when just drawn, a spoonful of an artificial heading made by whisking a solution of isinglass in sourish porter. This contrivance, however, does not effectually answer its intended purpose, as it may be distinguished from the genuine head by its not closing of itself when blown aside. A kind of heading that cannot be detected in the same way is made by adding to every barrel of beer half an ounce of a mixture composed of *green vitriol* (sulphate of iron), *alum*, and *salt*. This imparts also a degree of astringency to the beer, which porter drinkers sometimes prefer. So small a quantity of these salts is, perhaps, not injurious to health; the same salts are found in many mineral waters used as medicine; yet we should object to any mineral water, however weak, as a constant beverage; and, besides, this enables the publican to conceal a real defect in his beer. The law prohibits this practice.

3226. *To detect Sulphate of Iron in Beer.*—Fill two wine-glasses with the suspected beer; place them in a good light, and into one of these put a few drops of a decoction of galls; stir this well, and observe if the colour of the beer is changed on comparing it with the other glass; if the colour is blackened by the addition of the galls, this is a proof that the beer contains iron; and if the beer remains for four-and-twenty hours, probably the iron will be more distinctly manifested by the deposition of a blackish sediment.

Salt is likewise sometimes put into ale on account of the taste, which pleases some palates, and it is said to excite thirst. It does not appear to be a useful addition.

Sect. VI.—On the various kinds of malt liquor.

3227. *A great variety of fermented liquors have been prepared from malted grain in different periods* and in various places; but our object at present is only to consider such as belong to this country, briefly touching upon those which are made upon the Continent. Perhaps we cannot render this subject more intelligible than by prefacing it by a slight sketch of the history of our malt liquors, without attempting the depths of antiquarian research, for which, indeed, like many of our domestic habits, the materials are extremely scanty.

Subsect. 1.—*History of Malt Liquors.*

3228. The particular mode in which barley and other farinaceous grains were originally employed in fermentation is unknown.

3229. We are informed by Herodotus and by Diodorus Siculus that the Egyptians prepared a drink from barley not much inferior to wine; and we are told that this material was used because the vine did not grow in Egypt, a circumstance rather extraordinary, since it was so well known in Palestine, and is found in Egypt at present. However this may be, it is easy to account for the use of barley for fermentation in those European countries which were not favourable to the growth of grapes. Tacitus, Pliny, and other classic writers bear testimony to the existence of an intoxicating beverage made from malted grain among the ancient Germans and Gauls, and this was, no doubt, at the same time generally known among the Celtic nations in the north of Europe: it is not certain what grains were used, if any, besides barley.

3230. The possession of barley, or any of the farinaceous grains, supposes agriculture; and in ancient Britain, while only a small portion of the land was cultivated, mead produced from honey appears to have been long a general and favourite beverage. Raw barley does not readily ferment of itself, a decoction becoming rather sour than vinous; hence the process of malting was employed, and the addition of bitters is of great antiquity. The name for ale, in the ancient British language, was *cwrw*, which still remains in Wales. The term ale appears to have come from the Danish *oela*. The English word beer is synonymous with the German *bier*, and may be traced from the Saxon *bere*, barley: a variety of that grain is still called *bere* in Scotland. The French *bierre* and the Italian *birra* were derived, no doubt, from a similar source, and perhaps all may have had their origin in the Hebrew בר, corn, pronounced *ber*. The drinks in general use among the early Anglo-Saxons appear to have been mead and beer: ale and alehouses are mentioned in the laws of Ina, king of the West Saxons, in 728. Wine was not introduced into this country till a date somewhat later. The grape appears to have been cultivated at an early period in the monasteries, and after the Norman conquest it became more general among the nobles and higher clergy; but the other classes adhered to their ancient beverage, which became more plentiful, and more within the reach of the mass of the population, when, from the abolition of the feudal system, and the more settled condition of the country, agriculture was more attended to. The vineyards were neglected about the time of the Reformation, when many of the ecclesiastical gardens were destroyed. Ale then became the general and favourite drink.

3231. A variety of substances were added to the ale of our ancestors, as we have stated, for the purpose of overpowering the sweet, mawkish taste of the liquor fermented from barley, as well as to take away that tendency to acidity which is possessed by all malt liquors. The use of honey in brewing is of great antiquity, both here and on the Continent; this is still found an excellent addition in domestic ales, and it is said to be used by some public ale brewers in Scotland and England. Dubrunfaut, in some experiments on brewing, found that he could make a beer, much resembling the famous beer of Louvain, by fermenting wort without hops, and with the addition of honey. Bitter herbs were formerly infused in ale, not merely for ordinary beverage, but were added in great variety to compose what was called *herb ale*, a favourite medicament of those times: this was compounded by our ancient dames, as well as by the *leeches* of that day, who were the principal herbalists and apothecaries; but probably most of these additions were made to the ale after it was brewed, and were not considered as essential to its formation.

3232. A kind of malt liquor called *mum* is mentioned among the ancient drinks of this country as remarkable for the number of its flavouring ingredients. *Spiced ale* is continually referred to; and coriander, caraway, and other seeds were often added; also ginger, orange peel, orris root, &c. Many of the bitter substances, as wormwood, quassia, gentian, &c., continued long to be employed by our public brewers, until all but hops were excluded by the Legislature.

3233. We learn from Beckmann that the first notice of the use of hops occurs in the beginning of the fourteenth century, when it appears that they began to be regularly employed in the breweries of the Netherlands. They were introduced into English brewing in imitation of the Flemings, and were first imported from the Netherlands in 1524. But though their efficacy was admitted in the conservation of beer, yet they were long supposed to contain qualities noxious to the constitution, among which it was said that they "dried up the body and caused melancholy." Accordingly, we find in the household regulations of Henry VIII. an order to the brewer not to put any hops into the ale. They are first mentioned in the English statute book in 1552.

3234. In 1557 the national taste had somewhat changed in their favour, and Tusler, in his treatise on Husbandry, thus sings their praises:

"The hop for his profit I thus do exalt,
It strengtheneth drink, and it flavoureth malt;
And being well brewed, long kept it will last,
And drawing abide, if ye draw not too fast."

Their use was general in 1600, and their mode of cultivation was pointed out by Walter Blythe in 1653, in the reign of James I. It is evident from this that the beer of the previous periods had been very different from what it is at present. Soon after the introduction of hops into England, so little did they suit the general taste, and such was the public opinion respecting their deleterious qualities, that, about 1650, the Common Council of the City of London petitioned Parliament against two nuisances: one of which was "Newcastle coals, and the other hops; in regard they spoiled the taste of drink and endangered the health of the people." Hops were also petitioned against in the reign of Henry VI., as "a wicked weed."

3235. It is therefore probable that ale had originally but a small quantity of bitter, and was either not calculated for keeping, being drunk very new, or that it was prepared with honey without bitters, as is practised in the south of France and other places, and perhaps bottled or kept in some kind of close vessels, being rather a species of barley wine than like our modern ales. We find it stated in the "*Maison rustique*," 1616, that "the generall vse is by no means to put any hops into ale: making that the difference between it and *beere*, that the one hath hops, the other none: but the wiser huswiues do find an error in that opinion, and say the vtter want of hops is the reason why ale lasteth so little a time, but either dyeth or soureth, and therefore they will, to euery barrell of the best ale, allow halfe a pound of good hops." Thus the use of hops seems to have advanced gradually, partly from finding that it preserved the beer from turning acid, and partly from a taste for it now becoming habitual. Many of the herbs formerly thought to give an agreeable flavour would not now, perhaps, have many admirers, which is not surprising, since few persons like porter who are not used to it. It is curious to observe that the mode of brewing in Scotland was formerly nearly the same as that followed on the Continent (see Subsect. 3, "Scotch ale," and Subsect. 4, "Account of the Beers on the Continent"). But this agreement is the less remarkable, when we consider the correspondence in the architecture and many circumstances in their habits, owing to their political connexion. The invention of porter, which was quite peculiar to England, has produced a great change in the taste of the public with respect to malt liquors in South Britain.

SUBSECT. 2.—*Porter.*

3236. *Porter is a malt liquor peculiarly English:* the chief difference between it and ale is, that the former derives a dark colour and astringent taste from the use of brown or highly dried malt; from its having more hops than ale; and from the saccharine matter having been more exhausted in the fermentation, or, as the brewers say, having the attenuation carried farther, so that porter, as contrasted with ale, may be considered as a *dry* malt liquor. From these circumstances this beverage has been preferred in England, being considered as more wholesome than ale, when made, as it ought to be, from pure malt and hops.

3237. *The origin of a beverage so extensively used in the British dominions* is curious enough, and is thus stated by Malone:

"Before the year 1730, the malt liquors in general use in London were ale, beer, and twopenny, and it was customary for the drinkers of malt liquor to call for a pint, or a tankard of half and half; that is, half of ale and half of beer, or half of beer and half of twopenny. In course of time it also became the practice to call for a pint or tankard of *three threads*, meaning a third of ale, of beer, and of twopenny, and thus the publican had the trouble to go to three casks, and turn three cocks for a pint of liquor. To avoid this inconvenience and waste, a brewer of the name of Harwood conceived the idea of making a liquor which should partake of the united flavours of ale, beer, and twopenny. He did so, and succeeded, calling it *entire*, or entire butt; and as it was a very hearty and nourishing liquor, it was very suitable for porters or other working people: hence it obtained the name of *porter*."

It would be no easy matter to ascertain what was the precise quality of the porter of that time, but it was very probably different in some respects from the beverage of the same name made at present, in consequence of changes in the ingredients and the mode of manufacture, likewise in the taste of the public, and also from enactments which have restricted the ingredients within narrower limits than they were once confined to.

The distinctive character of porter being its brown colour and acerb taste, derived from the highly dried malt, the depth of colour was supposed to indicate in some degree the strength of the liquor, and, while brown malt alone was employed, this was the case. But in consequence of the taxes on malt and the high prices it rose to during the late war with France, brewers paid more attention to the subject, and they found that the heat used in rendering the malt brown destroyed some of the saccharine matter, and thus that the deep colour of porter was produced at the expense of the most valuable part which gave strength to the beer. They were induced, therefore, to use pale malt for the fermentation, as producing more strength, and, in consequence, being less expensive; but as the beer from this was deficient in that flavour which had been produced by the use of brown malt, and which was so much valued by porter drinkers, and as the porter was paler than before, in order to conceal these defects, they had recourse to various colouring substances and drugs of various kinds.

3238. *In consequence of a general complaint on this subject, an act was passed, in* 1816, by which all ingredients whatever, except malt and hops, were forbidden to be used in the making of malt liquor by the manufacturing brewer, as we before stated; and likewise all other substances to produce an artificial colouring, the chief of which had been burned sugar. Soon afterward, however, a discovery was made that in malt roasted almost black, in the manner of coffee, though the fermentable matter is totally destroyed, yet a large quantity of brown soluble colouring matter is produced; and as this substance comes within the letter of the act, a patent was taken out for it, and it is at present the practice among many, we believe most, of the brewers, to use a quantity of this to give the porter a deep colour.

This roasted malt is perfectly innocent, but gives no additional strength to the beer; and a dark-brown colour is in this case no indication of the strength of the liquor. Some brewers, however, we are informed, still employ only a mixture of pale and high dried or brown amber malt.

3239. *In the ordinary mode of brewing porter* the products of all the mashings are mingled together, and they constitute what is called *entire* beer. It is fermented with more rapidity than ale, and more of the saccharine matter is decomposed, since the liquor is not to be sweet: hence it is more liable to pass into the acetous stage, and requires to be put into cleansing barrels the moment it has arrived at a certain point. As, notwithstanding, it still contains much unfermented matter, it requires slow fermentation for a considerable time to convert it into alcohol; and some time ago this was thought to be best done in large masses. Accordingly, the brewers had immense store vats for this purpose, in which the beer remained for twelve or eighteen months; some of these vats held above 6000 barrels of porter; and that of Messrs. Meux held 18,000, and was said to have cost 10,000*l*. The porter, during its long repose in these vats, became spontaneously fine, and by a slow fermentation had all its saccharine matter decomposed, so as to be in the state of dry wine. The bitter also became less perceptible, and, from being kept so long, the beer was at length nearly what is technically called *hard*, that is, it was brought to the verge of acidity, without being at all acid.

3240. The explanation most to be depended upon of the terms *hard*, *stale*, *mild*, and *entire* porter may be found in the information given by Mr. Barclay, the celebrated brewer, to the committee of the House of Commons, in 1818. From this it appears that every publican has two kinds of beer sent to him by the brewers; one is called *mild* beer, which has been sent exactly as it has been brewed; and the other is called *entire*, which is a mixture of beer brewed for keeping, or what has been termed *hard* beer, waste beer from various sources in the brewery, and what has been returned by the publican, together with some beer of better quality; this is put all together into a vat and kept till it is bright. As there are various tastes, some prefer mild or fresh beer, and others the hard or stale beer, and some mix them: but it is supposed that the public taste is changed from what it was formerly, most persons now giving the preference to *mild* porter, what is called *stale* being too frequently almost in the commencement of the acetous stage, which renders it unfit for certain constitutions.

Here it may be proper to mention that when this is found to be the case, a slight degree of acidity can be corrected in a very easy and convenient manner by a little carbonate of soda, which is now kept for this purpose in every apothecary's and druggist's shop, and sold for about 2*d.* per oz. About a quarter of a small tea-spoonful, or less, put into a half-pint glass of stale porter, produces, when stirred, an immediate effervescence, and destroys the acidity of the porter. Too much soda will give an unpleasant alkaline taste, but the neutral salt formed by its union, and the acetous acid of the beer, acetate of soda, is by no means hurtful, being slightly laxative. This is particularly proper for persons inclined to dyspepsia who drink porter.

3241. *What is called brown stout* is, or ought to be, a superior kind of porter; but nothing can be inferred from its mere colour, that being artificial: it is about twenty shillings a barrel dearer than common porter. *Dublin stout* is an excellent kind of porter, which is thought to be quite equal to the London porter, and is a proof that good porter may be brewed wherever sufficient care is taken. *Porter for bottling* is also a superior kind, about ten shillings a barrel dearer.

Porter is scarcely ever attempted to be brewed in private establishments, though, if required, any one skilled in other malt liquors would find no great difficulty in preparing it.

Subsect. 3.—*Ale*

3242. *Ale is sweeter than porter*, and London brewers' ale is stronger. The ale from various London brewers differs in some particulars of strength or flavour; and the same is the case with what is brewed in different parts of the country: thus, Wiltshire ale is remarkable for being hard, as are the ales of the west of England generally; but those who are accustomed usually prefer it.

3243. *Burton Ale.*—This ale, so named from the place where it is made, Burton-upon-Trent, is in high repute in this country, and is exported to different places on the Continent. It is the strongest of our ales, being about 25 per cent. stronger than brown stout. It is of a somewhat thick, glutinous consistence, and agreeably sweetish taste. A small quantity of it produces inebriation with those persons who are not accustomed to it. Its colour is pale, and it is made from the very best pale malt and hops. Much of its intoxicating quality has been attributed to cocculus indicus; but of the truth of this assertion we have no positive knowledge.

3244. *Scotch Ale.*—The Scotch, particularly the Edinburgh ales of the present day, made partly on the old plan, are esteemed equal, if not superior, to any in Britain; and certainly some of the best Scotch ales have a flavour extremely vinous, and approaching the nearest of any of our ales to some of the light French wines. They are particularly mild in their flavour and pale in colour, and the taste of the hop does not predominate. One great advantage which they derive from the smallness of the quantity of the hops which they contain is, that it does not form a disguise for injurious ingredients, as is the case with the larger proportion used in English ales; and hence, if no better reasons could be assigned, it is said that the Scotch ales are less liable to adulteration than those of England. But, on the other hand, they are more difficult to keep long; and the fine Scotch ales are therefore generally bottled.

The principal difference between the manner of brewing Scotch and English ale is, that the former is fermented with a much lower heat than the latter, usually as low as 50°: this fermentation is slow; it continues for a fortnight, or even three weeks. The fermentation is carried nearly as far as possible in the fermenting vat, and hence it soon becomes fine, and is then put into casks, and is seldom racked.

3245. *It appears to have been the ancient practice in Scotland*, as it is still in some places on the Continent, to put the new fermented ale quite hot into casks, where the fermentation was carried on slowly, the bung-holes being left open, or loosely stopped with covers of clay. The ale was then sent out in this fermenting state to the customers in casks or in flagons; but it was afterward always bottled, whether strong or weak, and was generally ready in the course of a week. The low degree of temperature at which the fermentation is carried on confines the brewing to the colder parts of the year; and during four or five of the summer months no strong ale is brewed. The ale of Preston Pans is the finest and most vinous of the Scotch ales.

3246. *In Edinburgh, Dr. Thomson informs us, it was the custom formerly for the brewers to "send out the small beer in casks* the moment it was mixed with yeast, and before it had undergone any fermentation whatever." It fermented sufficiently in the small casks in which it was sent to the customers, who generally bottled it, which made it clear and very brisk, and extremely agreeable.

3247. *Welsh Ale.*—Mr. Donovan informs us that there is nothing peculiar in the process of making the excellent ale of that country. They brew rather small quantities at a time, use good malt and hops, spare neither, and take but one extract from the malt.

3248. *Windsor Ale.*—It is said that this contains a considerable quantity of honey and liquorice, which gives it additional strength. The honey is put in just before the liquor is run off into the coolers.

3249. *India Pale Ale.*—This ale was first prepared for the India market, but has lately come into general use here. To make it keep in a warm climate, it has more than the usual quantity of hops, and is, of course, much more bitter than the ordinary ales. It has been recommended by some physicians as being proper for certain invalids, with whom the usual ale does not agree. It is said that some brewers, in preparing it, merely add an infusion of hops to some of their already brewed ales.

3250. *Table ale and table beer* are weak ales, and in domestic brewing are generally the result of the second and third mashings: strength is not so much required as the right proportion of bitter, and perfect soundness and transparency. They are very wholesome beverages when in their sound state, and, when bottled, are excellent.

In London, professional brewers who brew ale and table beer are distinct from those who brew porter, and some brewers confine themselves to the manufacture of table beer only. They make this malt liquor from the best pale malt, or amber and pale malt. They usually draw six barrels of beer from one quarter of malt. The quantity of hops is from four to five pounds per quarter of malt. Being sent out in small casks, by proper management it may be drunk fresh and in good condition; it is not calculated for long keeping.

Subsect. 4.—*Some Account of the Beer made on the Continent.*

3251. It may be interesting to state a few particulars respecting the kinds of malt liquor made by our Continental neighbours, who differ from us somewhat in their taste on this subject.

3252. *The beer commonly drunk in Paris* is very different from any generally used in London. The French, accustomed to light wines, make their beer upon a somewhat similar principle. They wish rather for a refreshing than an intoxicating beverage; and their beer is admirably adapted to the purpose for which it is intended—a cheap refreshment at the theatre or promenade. It contains but little alcohol, and is more remarkable for its briskness than strength: being bottled when new, it ferments in the bottle; a great quantity of carbonic acid is generated there, which, when the cork is drawn, flies out with great violence, like our spruce beer. Good table beer, bottled with a little sugar, comes pretty near to it. In many parts of the Continent they prefer this light beer.

3253. *Malt liquor is a beverage much more common in Flanders and Germany than in France;* the best beer is brewed from malted wheat mixed with malted barley; the first grain gives a peculiarly agreeable flavour. We have an interesting account of the Flemish beer from Mr. Richardson, a late celebrated English brewer. At Brussels they have two sorts of beer; one of a brownish-amber colour, called *picterman*, strong and tolerably transparent, of a taste between bitter and sweet, but which, from not being well manufactured, is very liable to turn acid in warm weather. The other sort of beer, called the "*bierre blanche de Louvaine*," or *white beer of Louvaine*, is found throughout the Netherlands, and its manufacture constitutes the principal trade of Louvaine. The white beer is sweeter than the picterman, and much weaker. It is pale and turbid, and of the strength of table beer. Being bottled when it is new, it is extremely brisk. This is much relished by the Flemings, who consider it as a very wholesome and refreshing beverage; and although Mr. Richardson brewed for them some excellent beer in the English mode, which they praised highly, yet they continued to adhere to their accustomed beverage, which had pleased the palates of their ancestors, and which, though less scientifically made than ours, had less intoxicating effect. A similar beer is made at Berlin.

The white beer of Louvaine is made from *air-dried malt*, which was probably the original way of preparing it before kilns were employed. In Flanders and in Germany they dry their malt by spreading it on the floors of large lofty rooms which are attached to every brewery; and the process can only be performed in the summer months, when the temperature is sufficient for the purpose. The fine ales were probably first intended to imitate the brisk white wines as nearly as possible, and, consequently, the paler and clearer the malt, the fitter it was for the purpose. The proportion of hops in the Louvaine beer is very small, and the fermentation is carried on at a low temperature; yet, in some places on the Continent, beer is not fermented before it is barrelled, but, after mashing and boiling, is put hot into the barrels, in which it ferments spontaneously. Brown malt seems to be peculiar to England, where porter originated.

3254. *In Germany a great deal of malt liquor is drunk*, made wholly from malt and hops. *Bavaria is celebrated for its beer.* Liebig states, in his work on "Chemistry applied to Agriculture and Physiology," that the Bavarian beer possesses the property of not becoming acetified, even *when kept in vessels half filled.* "This valuable quality is obtained for it by a peculiar management of the fermentation of the wort." "The wort, after having been treated with hops in the usual manner, is thrown into very wide flat vessels, in which a large surface of the liquid is exposed to the air. The fermentation is then allowed to proceed, while the temperature of the chambers in which the vessels are placed is never allowed to rise above from 45° to 50° Fahr. The fermentation lasts from three to six weeks; and the carbonic acid evolved during its continuance is not in large bubbles, which burst upon the surface of the liquid, but in small bubbles, like those which escape from an acidulous mineral water, or by a liquid saturated by high pressure. The surface of the wort is scarcely covered with a scum, and all the yeast is deposited on the bottom of the vessel in the form of a viscous sediment." In this practice the principle appears to be, to render the fermentation very complete, and to exhaust entirely the ferment, or to render it incapable of exciting fermentation of any kind, and, of course, arresting any progress that might be made to acescency. It is farther stated that the various kinds of beer manufactured in Bavaria are distinguished by different flavours, which are given by allowing small quantities of the herbs and blossoms of particular plants to ferment along with the wort. The price of beer in Bavaria is regulated by law every year, according to the price of barley, and there is but one strength of beer made, the duty on malt amounting to half its value. The strength is a quarter of malt to three barrels and a half, or rather less, of beer. The summer beer, when made, is first put into large open barrels used for the slow fermentation, during which time small casks are filled from them, and sent out daily to the publican for immediate consumption. The winter beer is put into closed casks, and is as bright as wine, and extremely brisk. The beer of Augsburgh is remarkable for having a pitchy taste, communicated purposely by pitching the inside of their store vats.

3255. *Prague is also famed for beer*, which is reckoned next in quality to the Bavarian. The beer vaults of Prague are of the very best kind; and, as the floor of the cellar is always covered with a thick layer of ice, on which the casks of beer are placed, the beer is sent out to be drunk in a chilly state.

3256. *In Brunswick* a remarkably strong beer is made, called *Mumme*, and large quantities of this used to be imported in the latter end of the sixteenth century, when it was mentioned in the excise laws. This German beer was made in the towns of Lubeck and Rostock, which were famous for its production. So great was the trade in it, that 800,000 barrels were annually exported under the name of *Lubeck beer*. The city of Rostock contained 250 licensed breweries; and the most considerable part of the Duke of Mecklenburgh's revenue arose out of the excise laid on the beer brewed in these cities. This strong Lubeck beer was produced by using double the usual quantity of malt of wheat, with oatmeal and beans; but besides these, it is said that there were in it also infusions of fir and birch tops, majoram, pennyroyal, wild thyme, elder flowers, seeds of cardamom, and barberries; so that it appears to have been analogous to the herb ales of our ancestors. In the excise laws, mention is made of a similar *mumme* having been made formerly in Ireland.

3257. *The national drink and the ordinary household beverage of Russia* is the far-famed *quass*, which is made by fermenting an infusion of barley malt, rye malt, and rye flour that has been roasted in iron pans. It is extremely popular from the emperor to the peasant; but, except when flavoured with fruit, it is "sour, weak, watery, and unpalatable." Of this, George Jubervill, one of our poets in Queen Elizabeth's time, says:

> "Such liquors as they have, and as the country gives,
> The one called kuas, whereby the Russie lives,
> Small ware, water-like, but poor in taste."

SECT. VII.—VARIOUS KINDS OF CHEAP BEER MADE OF OTHER INGREDIENTS BESIDES MALT AND HOPS.

3258. *Beer may be made without barley.* Not only can any farinaceous grain be converted into malt by the process of germination already described under "Malting," but any substances containing either starch or sugar may be made to afford beer with the addition of hops, or some similar bitter substance containing the astringent and bitter principles. The various substances containing these constituents would no doubt require each a peculiar management; but it is important to know what substitutes may be used in various countries, or under peculiar circumstances. To understand this, we should keep in mind what has been stated above, that the only use of malting is to convert the starch of the grain into sugar, and thus to produce a cheap kind of it. Whenever we have starch, it is possible to produce sugar by some process or other; and whenever we have sugar, we can ferment it into spirit or alcohol. The chief peculiarity of ale and beer is that, in addition to the spirit, they are flavoured with an aroma or essential oil from the hop, and likewise with an astringent bitter from the same plant, which is supposed to assist its preservation or keeping; and though we might not be able to produce from other materials a beer exactly like that from malt and hops, barley, or some farinaceous grain, yet beverages nearly analogous may be made with any material containing sugar, and any bitter nearly resembling hops. Many such beers have been made, and found very agreeable and useful. We shall give examples of them.

3259. *Sugar Ale and Beer.*—Cane, or common sugar, is somewhat different from the sugar of malt; but it may be fermented equally well into a beverage which some have even preferred to malt liquor. One great advantage of this beer is, that the process of making it is much more simple, and more easily performed, no malting or mashing being necessary; the apparatus is also much less complicated. To make ale, procure a ten gallon cask, set it on its bottom, and fit the head in. Put a cock into the side, one inch above the bottom, and make a hole in the head, and close it with a bottle cork. Put a pound and a half of hops into any convenient vessel, and pour on them eleven gallons of boiling water; or, if there be a copper large enough, boil the hops in the water for five minutes; strain off the hops, and add fourteen pounds of sugar to the strained liquor; mix one pint of good yeast with this, and put the whole into the cask through the hole in the top; it will soon ferment, and the yeast will appear through the hole in the head; as this works out, let it fall back again into the hole. It will require, in summer, about three weeks or more to complete the fermentation, and as this slackens towards the latter part, the cork should, for the most part, be kept in the hole, to prevent the access of too much air, which might be apt to occasion sourness; but the cork should now and then be removed, to give vent to the fixed air that collects. When the fermentation has stopped, and the sweet taste of the sugar is barely perceptible, the cork must be driven in tight, and in four days the beer will be fit for draught or for bottling. Care must be taken to ferment sufficiently, but not so long as that the liquor becomes flat, as it would then soon sour. White sugar will afford a liquor of the purest flavour and palest colour, but brown sugar will answer. If a deeper brown colour be wanted, which many would think a disadvantage, it may be given by burned sugar. The drink will fine itself, and the grounds will settle in the space below the cock, for which purpose it will be best to have room enough to prevent the beer from drawing off foul.

Mr. Donovan describes this beer in terms of high praise. He states that "there is a purity of taste belonging to it quite different from the indescribable jumble of tastes so perceptible in common ales, and a light sharpness combined with tenuity, which is much more agreeable than the glutinous or mucilaginous softness of even the best ales. But it has one advantage which places it above all competition, and that is, its lightness on the stomach; this, when compared with the sickly heaviness of malt ale, is really remarkable. The whiter the sugar, the lighter the ale will be; and age greatly conduces to the same end, provided that the drink is sound, which is best ensured by bottling." It is scarcely necessary to observe that the strength may be increased, or diminished to that of table ale, by using more less of the sugar and hops.

It is reckoned that ten pounds of Muscovado sugar are equal to a bushel of malt.

3260. *Beer from Malt and Potatoes.*—We are told by M. Dubrunfaut that he made a beer as follows, which, when bottled, very much resembled the brisk beer so much used in Paris: Potatoes were grated to a pulp; this was well mixed with boiling water, and some ground barley malt was added. The wort being drawn off after mashing, it was hopped in the usual way; yeast was added, and the whole fermented. The proportions are not mentioned, but any one acquainted with brewing would find out how to supply this. Here the starch of the potatoes is converted into sugar in the mashing through the means of the malt, in the same manner as in the case of raw barley.

3261. *Beer from Treacle alone.*—Get 14 lbs. of treacle and 6 oz. of hops; boil them together for two hours in 11 gallons of water; when cooled sufficiently, add a proper quantity of yeast; let it work in a tub covered up for 16 hours; when the working is over, put it into a cask; let it work there, as usual, for two or three days; then bung it down, or pour it from the lees, and bottle it. The beer will be fit to drink in a week, and be as strong as porter. It will cost only 1½*d.* per quart. If not sufficiently fermented, it will be apt to be too sweet. The great defect in treacle beer arises from the want of mucilaginous matter in proportion to the saccharine part of the treacle. A better kind is made from treacle and barley. A little ginger may be added, if wished. If required to be of the strength of table beer only, use more water in proportion to the other ingredients.

3262. *A very wholesome and palatable ale has been made by using mangel wurzel instead of malt.* After the roots are well washed, and the tops cut off, they should be scraped, that the outer rind may be taken off: they are then sliced, and boiled till they are soft. The liquor is squeezed out from them by some kind of press, and it is boiled with hops, in the proportion of six ounces of hops to nine gallons of juice. This is next worked with yeast in the usual way. The roots will keep during most of the winter if put into a cool place. Ten pounds of the root should afford a gallon of juice; but if fifteen pounds is allowed, the ale will be strong. Two pounds of treacle to a firkin will be an improvement; or one third malt and two thirds mangel wurzel may be used as still better.

3263. *Spruce Beer.*—This name is given to a very wholesome effervescing beer made from molasses and the extract of the spruce fir. *Brown spruce beer* is prepared in the following manner: Add to eighteen gallons of boiling water from twelve to fourteen pounds of molasses, and from fourteen to sixteen ounces of extract of spruce, commonly called essence of spruce. Suffer the mixture to cool, and when lukewarm, add to it one pint of yeast, and ferment the mixture. In warm weather less yeast will suffice. While the fermentation is going on, remove the yeast by skimming, and when the fermentative process begins to become languid, which usually happens in two days, let the beer be put into stone bottles, and the corks tied down with pack-thread. Sugar is preferable to molasses, and if malt wort of an ordinary strength be substituted for the water, a spruce beer of a very superior flavour is obtained. Some ferment it in a cask before bottling it. Spruce beer is, in fact, a treacle or sugar beer flavoured with essence of spruce instead of hops. *White spruce beer* is made in a similar manner, by substituting for molasses white or brown sugar. This drink is considered as an anti-scorbutic; and, in cold countries, ships that intend to brew their own spruce beer should carry the yeast in bladders or closed casks.

3264. *Most of the above-mentioned kinds of beer,* though extremely useful as cheap substitutes, and extremely wholesome, will not be considered, in general, as equal to good beer made from malt and hops only; yet, when well made, the difference is less than most persons might imagine, and the economy is very material. Great care should be taken not to suffer them to become sour, by keeping them in a very cool place, as beer in the least acid is extremely prejudicial to health.

Sect. VIII.—Management of the Beer-Cellar, and Storing of Beer.

3265. *In order that the temperature* of the cellars in which malt liquors, as well as others are kept, may be as uniform as possible, vaults are constructed for this purpose underground, as the changes of heat from the seasons are observed not to operate beyond a very few feet below the surface of the earth. This attention is the more necessary for beer, as this liquor soon comes to a state of fermentation by a heat above 55°, sufficiently great to exhaust its remaining fermentability, and then it will become vapid and sour, for the reasons which have been already stated. If, on the other hand, the temperature of the cellar should ever descend to the freezing point, and the beer should become frozen, it will be separated into distinct substances; the water and mucilaginous part will pass into the state of ice, and its small portion of spirit will collect in the centre, where, even if it should remain perfect till the returning heat again dissolve the ice, the other parts of the liquor never again combine with it in the same homogeneous fluid which it was before, its flavour is totally lost, and it remains fit only for distillation, or to be converted into alegar, a kind of vinegar.

3266. *The ancients used a very simple method for preserving their liquors* from change of temperature. They kept them in large earthen-ware vessels holding several gallons, which they placed in holes dug in the earth, thus burying them beneath the surface until the liquor was sufficiently meliorated by age; and with us store vats are sometimes sunk in the ground; but there are inconveniences attending this on account of leakage.

3267. *Great attention is paid to the construction of cellars* in various parts of Europe, particularly the north, and if more care was taken in this respect here, much would be saved of the liquor that is now spoiled, and much of the sickness prevented which is caused by the use of acid liquors, which lay the foundation of more diseases than most persons suppose.

3268. *Malt liquors owe more of their effects to the carbonic acid gas united with them than wines;* and if it be so necessary to prevent this gas from escaping from brisk wines, we should bestow the same, if not more, attention upon ale and beer, if we wish to drink them in perfection. The confinement of the carbonic acid is the chief circumstance necessary for the preservation of malt liquors, after the requisite care has been taken of their fermentation.

3269. *From the time that air comes into contact with beer*, the latter proceeds more or less towards acetification; and for this reason, when the consumption is not sufficient to exhaust a large cask in a few days, the beer should be kept in smaller casks, proportioned to the weekly use of the family; for when part of the beer is drawn off, the air must come in contact with the whole of its upper surface, which, as casks are generally laid on their sides, is of large extent, in proportion to the quantity; and, according to the surface, the increase of acid will be more or less rapid.

3270. *Beer, to keep long in cask, should be brewed of good strength with that view.* The weaker it is, the more likely it is to turn sour, the tendency to acetify depending upon the smallness of the quantity of alcohol or of hops, each of which has a preserving power; and the production of acid is, in general, chiefly owing to the mucilage left in the liquor.

3271. *As soon as the casks are brought into the cellar*, the bungs should be drawn, and they should be filled up full with fine beer, skimming off from time to time the head that will arise in consequence of its being rolled over. After being attended to in this manner for two or three days, the casks should be bunged tight, and a hole bored with a gimlet near the bung, with a vent-peg or spile fitted to it, which should be left slack for a day or two.

3272. *In warm weather the beer is apt to ferment*, and a hissing may sometimes be perceived at the bung-hole or the vent-hole: when this is the case, the vent-peg may be loosened a little every day till the liquor has become quiet. The bungs and vent-pegs should be frequently examined in warm weather.

3273. *Tapping the Casks.*—Most persons at all accustomed to a cellar know how to tap a cask. In driving in the cock with a mallet take care to drive straight, for if put in crooked it is very likely to leak. When the greatest part of the beer is drawn out of a cask, it is necessary to tilt it, or make it lean forward a little, by means of wedges, which is called *stooping:* care must be taken not to shake the beer, lest it get thick.

3274. *The proper management of the vent-peg is of great consequence;* and it is necessary that the principle upon which it operates should be clearly understood.

It is well known that it is impossible to draw beer from a cask of which the bung is closed, except there is a small hole in the top of the cask, stopped occasionally by a peg. If there be no such hole the beer will not flow, because no air can get in to supply the place of what comes out. If a hole was constantly left open, all the carbonic acid disengaged from the beer would escape, and common air get in, which would soon cause the liquor to turn flat, and then sour. Therefore, upon putting the cask into its place, a small hole is bored in the top with a gimlet, and a peg fitted to it. On drawing a small quantity of beer for the first time from the cask, the peg is taken out, and air admitted, and then the hole is closed by the peg. After some time, when more beer is to be drawn, the peg is not to be taken out, for by this time some fixed air will have been disengaged from the beer, and will occupy the upper part of the cask, exciting a considerable pressure on the surface of the liquor in the cask, *fig.* 559. The beer will therefore flow out until the elasticity of the included air is brought down to that of the common air outside the cask. But it will flow somewhat longer than that, for the force which the beer by its own weight will exert to come out will occasion the air in the cask to be in some degree rarefied; but when it becomes so much so that its elasticity is less than a counterbalance to the pressure of the atmosphere upon the aperture of the cock, the beer will cease to flow. It is necessary, then, to take out the peg, and the air may be heard rushing in to fill up the vacancy made by drawing off the beer. As soon as the noise ceases, the peg must be carefully replaced; for, if left out, the beer would be spoiled. When the peg is replaced, some more may be drawn as before; but the flowing of the beer can only proceed to a certain point, and then it is necessary to take out the peg to admit air, and so on, till the whole is drawn off. It is evident, therefore, that the surface of the beer in the cask is constantly covered with a stratum of air; at first, this is chiefly carbonic acid, which will preserve the beer; but by degrees, as this escapes, and the proportion of common air increases, the beer will first become flat, and ultimately sour, if it remain long enough before it is consumed.

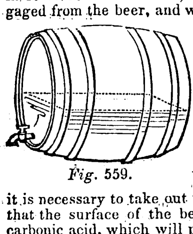


Fig. 559.

3275. *Beer, when once fit for use, should not be agitated.* The removal or disturbance of a cask of beer is always injurious, though none of the sediment called *grounds* or *lees* of the fermenting tub may have been put into the cask; but as some yeast is gradually produced by the slow fermentation, and is deposited in the form of lees, little motion will stir this up, and render the whole contents of the cask muddy; besides, such lees are liable to induce a new fermentation, which tends to spoil the beer. If it be required to transfer the beer into another cask, it must be done very carefully, without disturbing the sediment at the bottom. This is best effected by means of the siphon. It is also requisite that the cask should be tapped at such a distance from the bottom as to allow the beer to flow clear of that sediment which may have collected there.

Beer is sometimes injured during thunder-storms, and has been turned hard or sour—an effect not easily explained, although probably connected with the electricity of the atmosphere at the time; or, as some suppose, it may be occasioned by a tremulous motion induced by the thunder. To guard as much as possible against the agitation of the beer by this cause, the casks should not touch the walls or ground, but be placed upon wooden supports, which should be pitched and painted, to prevent rotting.

3276. *When beer has become hard in the cellar*, and it is desired to destroy this quality, some mix with it an equal quantity of new beer, and others add hops in the proportion of half a pound to a kilderkin, or, rather, boil the hops in some beer, strain the liquor, and put this in the casks, and then bung up; this in a few weeks will render the beer much more palatable. A better mode is to prepare a small quantity of fresh wort, and, after filtering it through a flannel bag, add it to the ale that is hard or flat in the proportion of a quart to a barrel; this will renew the fermentation in some degree, and give the ale briskness.

3277. *Methods of correcting the Acidity of Beer.*—Even after much care in brewing, malt liquors will sometimes become acid. On the first signs of acidity, it is necessary to do something to check, by the method just pointed out, what would, if neglected, ultimately cause the whole to turn sour.

Every degree of sourness in beer proceeds from a commencement of this acetous fermentation. If the change in the beer is perceived before it has gone too far, and when but a small quantity of acetous acid or vinegar is formed, it is possible to neutralize this, and to prevent for a time the formation of more.

The substances proper for neutralizing acids are alkalies and alkaline earths. The alkali usually employed for destroying the acidity of beer is carbonate of *soda*, and carbonate of *lime* is the only alkaline earth made use of. If carbonate of soda is used, it should be added very gradually, otherwise the effervescence will be too violent; its action may be observed by putting a little to some of the beer in a glass. The quantity must depend upon the degree of acidity of the beer; too much will communicate a very unpleasant taste. Marble reduced to fine powder (which is carbonate of lime) answers better; it dissolves slowly in the beer, of course giving out its carbonic acid as slowly. The lime dissolved forms, with the acetous acid of the beer, acetate of lime, which is slightly bitter, but harmless. There is another advantage in marble powder, which is, that there is no danger of putting too much; for no more lime will be dissolved than the acetous acid can take up, and the remainder will lie at the bottom of the cask without producing any effect.

Egg-shells and pounded oyster-shells have been recommended for this purpose; and they answer equally well, for these substances are likewise carbonate of lime, and exactly of the same composition as marble.

3278. *The machines now so much used for raising beer from the casks* in the cellar by the working of a piston and handle in the bar of a public house, are a great improvement; they prevent great waste from spilling and from pilfering, and might be advantageously employed in large domestic establishments; but care should be taken that their pipes are not made of lead, since, when that is the case, and beer should remain in them, it would dissolve some of the lead, and produce a poisonous liquid. Pipes of pewter are safe.

3279. *The late Mr. Bramah had a patent for a method of keeping beer or other liquors from the contact of air while on draught*, which deserves notice among the methods of preserving beer. This invention was intended for public houses of extensive custom, and was combined with the plan of elevating the liquor as it was wanted from the cellar by mechanical means, which is now practised so generally by other contrivances. To effect this purpose, a cylindrical cask of wood, *fig.* 560, was fitted with a piston, secured like that of a steam-engine; and on the top of the piston-rod was placed a box heavily loaded with stones, so as to press the piston down with force to the bottom of the vessel. The liquor was forced into this cylindrical cask beneath the piston from another vessel by a small forcing pump, till the piston was elevated to the upper part of the cask, and then the weight at top reacting on it, forced it to ascend in the pipes to the bar of the public house, where, on turning a cock, it was drawn as required. The piston in this apparatus, being always in contact with the liquor, preserved it effectually from the air till drawn off to the dregs. The chief difficulty, in the construction of this apparatus, would be the getting the piston to fit tight against the sides of the cylinder. It is evident that a common cask would not answer, not being perfectly cylindrical. Means have been invented, of late, for turning casks inside by a lathe prepared for the purpose, and have been used in some manufactories; and the cylinder or cask might be prepared in this way, or it might be made sufficiently round and smooth by a good joiner; but a cooper is not used to work of this kind. Some cork fitted round the edge of the piston would probably keep it sufficiently air-tight. The round form is not necessary, square or any other shape would answer.

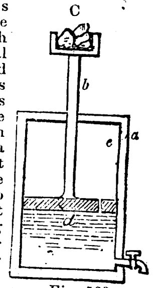

Fig. 560.

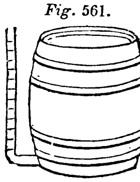
3280. *A method of preserving malt liquors* in the cellars was patented by Mr. Wynn, and is now sold by Thorn and Pedley, Castle-street, Leicester Square, London. This consists in an apparatus for generating carbonic acid gas from marble and sulphuric acid; this gas is then conducted into the upper part of the vessel from which the malt liquor is drawn for consumption, and the space in the vessel, left vacant by drawing the beer, is kept constantly filled with the carbonic acid gas, and, of course, all the common air is excluded. Such beer or ale will continue to the last as brisk as it was at the beginning of the draught.

Fig. 561.



3281. *A very useful contrivance has lately been made*, by which one may see, by simple inspection, how much liquor of any kind has been drawn from a cask, and how much remains in it, which can save all the trouble of gauging. A glass tube, *fig.* 561, is fixed in a perpendicular position, and connected with the lower part of the cask; and it is obvious that the surface of the liquor in the cask and in the tube will always be exactly level. This tube is graduated so as to show the quantity of liquor at any time in the cask. To graduate the tube, a certain quantity of liquor or water is put into the cask, and a mark made on the tube where the fluid stands; then another similar quantity is added, and another mark made on the tube; and in this manner, by pouring in equal quantities into the cask, and marking the place where the fluid stands in the tube, a scale is got on the tube which will correspond with the equal quantities in the cask.

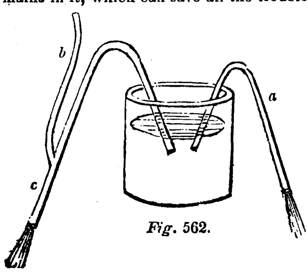


Fig. 562.

3282. *For transferring beer or other liquor from one vessel to another, a siphon* is sometimes found convenient, as by it the liquor may be decanted without disturbing the sediment, and also the liquor can thus be transferred without making any aperture in the lower part of the vessel. A siphon is a bended pipe, whose legs are of unequal lengths. For common purposes, the siphon of the form *a*, *fig.* 562, may be employed. To use it, the short end must be placed in the liquor to be decanted, and by sucking with the mouth, or other method, through the other end, it must be raised in the tube so as to run out; and it will then continue to run of itself until the vessel is emptied. But as sucking by the mouth is on many accounts inconvenient, the same effect may be produced by inverting the siphon, and filling it with the liquor; then keeping the two ends stopped with the finger or otherwise, introduce the short end into the liquor; unstop the ends of the siphon, and the liquor will flow. Sometimes the siphon is made of the form *b*, with an additional small tube to suck out the air by at first; a cock at *c* is then necessary, to shut till the tube is full, and it is then opened to allow the liquor to flow. Siphons of this kind are much employed by brewers and distillers. In the siphon it is essential that the leg through which the liquor flows shall be longer than the other, as the whole action depends upon this; for it is the greater weight of the fluid in the longer leg that overbalances that of the shorter leg. Small glass siphons are sold of both forms, *a* and *b*, and are found extremely useful for decanting many liquids, where it is desirable to draw the fluid from the top instead of the bottom, and where any disturbance would be injurious.

Sect. IX.—Fining Beer.

3283. *When malt liquor, properly made, is left to itself, all the floating impurities generally subside in time*, and the fluid remains clear and transparent. But sometimes this does not happen, or not sufficiently soon. In this case it is necessary to employ some method of hastening this subsidence of the floating matter that occasions its muddiness. The means of effecting this is called *Fining*.

In London, beer is often sent to the publican as soon as the fermentation is over, and before it has had time to become clear; it is then usual to send along with it a quantity of liquid called finings, and the publican puts a portion into each cask. Various substances are used to mix with beer to occasion the precipitation of the impurities, and rendering it clear and transparent; but the most usual of these is *isinglass*, and it is the only substance which the Legislature permits the public brewer to employ in fining.

But isinglass will not answer for fining, if dissolved in hot water; if added in this manner, it will coagulate and fall to the bottom without carrying the feculences with it. For this purpose it is dissolved in vinegar, or in very old, stale, or sour beer; and when it is once dissolved it is reduced by adding some mild beer to the solution. It should be stirred about well, and after this it must be strained through a hair sieve or coarse cloth: a brush is useful in forcing it through the sieve, when it should be of the usual consistence of beer, and it should be transparent. The quantity employed may be from a pint to a quart per barrel; but this proportion must necessarily vary according to the degree of foulness of the beer.

To try whether the fining will act properly, it is necessary first to make an experiment with it. Put some of the beer to be fined into a large half-pint vial, or tall clean glass of any kind holding this measure, and add to it a little of the finings prepared for use, taking the weight of what you use. Observe the effect which it has upon the beer. This effect will probably be, that the feculences will begin to collect in large fleecy masses, which will gradually rise to the top, leaving the beer perfectly clear. But the quantity of finings so employed may be more than is really necessary, and it is not desirable to have more isinglass in the beer than can be avoided. Make, therefore, another experiment with the same quantity of beer, but with less of the finings; and if the effect does not take place satisfactorily, of rendering the beer transparent, the first proportion must be adhered to. If with the smallest proportion of finings the beer is cleared, make another experiment with still less, and satisfy yourself that you have ascertained the least proportion of finings that will act decidedly, before you put the whole of the finings into the cask. To fix upon the right quantity of finings for the cask, ascertain how many half pints there are in the cask; say there are 200: then multiply the weight of the finings in the successful experiment by 200, the product will be the weight of finings for the beer. Many persons may not be disposed to take this trouble, but it is a more certain mode than mere guessing; and those who desire to be accurate will not object to it.

3284. *Fining should never be used but in case of necessity*, as any addition of this kind to the beer promotes acetification, an effect which the brewers well know, as they never add it to the liquor till they are just going to part with it; besides this, the stirring up the liquor is injurious, from risking a renewal of fermentation. Beer that has been fined, unless the cellar be particularly cool, is liable to turn sour, especially if it be of no great strength. Transparency, or *fineness*, as it is called, is essential to the keeping of beer; but this property should be the result of good brewing, and should not be produced by art.

3285. *The mode in which the fining operates* is, by entangling and combining with the floating undissolved substances suspended in the liquor, after which the action of the alcohol coagulates it in the same manner as it does whites of eggs; and the whole being specifically lighter than the liquor, it rises to the top, and, as is the case in some wines, it floats as a scum. This coagulated matter falls to the bottom if specifically heavier.

3286. *Several other substances may be used instead of isinglass*, although none answers better. Gelatin prepared from any material, as hartshorn shavings or ivory turnings, will give a jelly that will do. Albumen also may be used, as whites of eggs, or the serum of bullocks' blood. The sounds of cod-fish, being also the swimming bladder of that fish, is of the same nature as isinglass, and when well dried and treated as above described, will answer nearly as well for fining; but, when the quantity used is considerable, they are apt to leave a fishy taste in the beer. Mr. Donovan states that alum has been found to be a good substitute for isinglass; about an ounce in powder, dissolved in a hogshead of beer, will effect this purpose, without communicating any taste, or having any prejudicial effect.

3287. *Ropiness in beer* is a disease which sometimes occurs, and is supposed to be owing to ill-made malt; sometimes from an injudicious mixture of unmalted barley, or, perhaps, from too much mucilage being left in the beer. It is difficult to cure. Mr Black directs the beer to be put into a vat with a false bottom, and to add per barrel four or five pounds of hops taken gradually away after the first boiling of the wort; to this may be added about ½ lb. per barrel of mustard seed. The beer should be roused as the hops are gradually introduced, and in some months the ropiness will be cured. The beer should be drawn off from below the false bottom.

Sect. X.—Bottling Malt Liquor.

3288. *All kinds of malt liquor are much improved by bottling;* and this is, at the same time, accompanied by the advantage of its keeping in a brisk state. The liquor is improved and mellowed by the slow fermentation it undergoes; and the carbonic acid which is disengaged, being confined, is absorbed by the liquor: upon withdrawing the cork, and, consequently, the pressure, the imprisoned air escapes suddenly, and occasions the appearance of *briskness*.

3289. *To succeed in bottling malt liquors,* it is necessary to be particular as to their state at the time it is wished to bottle. The custom is, to leave a small portion of the saccharine matter unattenuated, or in a state fit for very slow fermentation in the bottle. But the fermentation should be *nearly* completed, for if it is not, too much air would be generated, and the bottles would probably burst: again, if the liquor is quite flat, it is of no use to bottle it, as, the fermentation being over, it would then turn sour. On drawing out the vent-peg of the cask, if the liquor spirts out with violence, it is evident that the fermentation is still going on; but if the liquor appears still, yet on tasting is found to be in good condition, and brisk, then it is ready for bottling. Should the beer appear a little too brisk and frothy while bottling, the bottles may be left open for a few hours, and filled up as the froth works out; but they should be filled only within an inch of the cork. It must be observed that, if the corks are driven in while the liquor is still working much, there is always a danger of the bottles bursting. Great care should be taken to bottle exactly at the proper time. When a cask of beer is to be bottled, it is usual to loosen the bung and leave the beer exposed to the air for a short time, as a day or two, to *flatten it*, to prevent the bottles bursting; but there is great danger if the beer stands exposed too long, it may contract a tendency to acidity.

3290. *The corks should be of the best quality;* there is no saving in cheap corks: soak the corks in a little of the beer; and when the bottles are corked they should be laid on their sides, that the beer, by swelling the corks, may make them quite tight. Should any of the bottles begin to burst, the whole should be set upright. They should be kept in a regular temperature. If the beer is in perfect order (and it should not be bottled except it be clear), there is no occasion for any addition; but if it be a little too flat, or if it is wanted to *be up*, as it is called, very soon, a lump of sugar may be put into each bottle, or four or five raisins, or a tea-spoonful of rice: these, by giving rise to a new fermentation, will make the beer very brisk. The warmer the weather, or the warmer the place where the bottles lie, the sooner will this fermentation begin, and the beer be ripe and fit for use. Strong ales may be kept in bottles of glass, without the risk of forcing out the cork or bursting the glass, but weak ales undergo a much more violent and unmanageable fermentation than strong ones; hence table beer in warm weather may burst the bottle, while strong ale will not be affected. In some kinds of beer, where there is much fixed air generated, and where glass bottles would not be sufficiently strong, earthen-ware bottles, called *stone bottles*, such as those used for spruce beer, will be best, and the corks of these require to be tied down with string or wire. Great care should be taken that the bottles are perfectly clean; and one great advantage of glass is, that its transparency enables this to be easily seen.

3291. *When a small cask of ale or beer of any kind is half consumed*, it is a good practice to bottle the remainder, which otherwise would get too flat; but in this respect attention must be paid to the time when it is required to be fit to drink. Beer of any kind to be bottled for exportation should be brewed of good strength to ensure its keeping.

Sect. XI.—Strength of malt liquors.

3292. The strength of malt liquors depends, like that of wine, upon the quality of alcohol or spirit of wine which they contain.

Experiments by Professor Brande on this subject have given the following quantities of alcohol in 100 measures of various malt liquors, and therefore the numbers exhibit their relative degrees of strength:

	Parts of alcohol by measure.		Parts of alcohol by measure.
Home brewed ale	8.30	Another sample of London porter	4.20
Burton ale	6.25	Another do.	4.44
Another sample of do.	8.88	Do. bottled	4.75
Edinburgh ale	6.20	Brown stout	5.00
Dorchester ale	5.50	Another sample of do.	6.80
London ale	5.80	Small beer	0.75
Scotch ale	5.75	Another sample of do.	1 28
London porter	4.00		

CHAPTER IV.

ON WINES.

Sect. I.—general principles of making wine.

Subsect. 1.—*Introduction.*

3293. Few of the articles used in domestic economy require to be well understood more than wine, both on account of its expense, and its effect on health; yet there are few with respect to which accurate knowledge is less generally diffused, owing, probably, in a great measure, to this not being a wine-making country: hence the various circumstances of its manufacture are but little known.

We propose to divide this subject into several sections. In the first, we shall treat of those theoretical principles upon which the production of wine, whether foreign or domestic, depends. *In the second part*, we shall enter into a description of the properties of those foreign wines which are most generally known in Britain. *In the third*, we shall consider the methods of fabricating wines from our native British fruits, or what are usually termed *domestic* or *home-made wines*, and particularly the most perfect, those made from grapes. *In the last*, we shall treat of the business of the wine-cellar, and the adulterations of wine.

3294. *Wine having been made long before chemistry was known as an art*, its discovery did not depend upon this science; nor is it to be supposed that much chemical knowledge is possessed by all who make good wines at the present day. The art of wine-making attained a degree of perfection, no doubt, chiefly in consequence of an infinity of trials made by persons who had sense and intelligence sufficient to take advantage of observations made during the various processes they employed, and who could mark certain effects, although they could not describe the rationale of them. In countries where the necessary materials are abundant, and other circumstances are favourable, this is comparatively easy; and good wine is often made, like good beer, by persons who acquire a certain skill which they do not know how to communicate, but which is the result of what is sometimes denominated *mere* practice, although, in fact, it is practice guided by sagacity and careful observation. The experience of such persons generally dies with them, and similar knowledge can only be obtained by going over the same ground again, and by the repetition of numerous experiments, many of which must necessarily be unsuccessful.

3295. *It is the business of science to shorten this labour* by recording the precise results of the several trials, and, by pointing out the natural causes that have acted in producing them, lead the way to a more certain mode of practice. By studying the scientific principles of any art, we obtain in a short time a degree of knowledge that otherwise could be acquired only by long experience, and with this advantage, that it is unattended with those prejudices which are usually possessed by those who have devoted much of their time to practice only, unaided by the lights of science.

In Britain, our climate being unfavourable, the art of making wine is little practised; it is, therefore, more difficult to gain experience, and we have the more occasion to profit by that of others. France has long preserved a superiority in the fabrication of wines, although for many ages the art of wine-making had been conducted according to empirical rules; but it was in that country that chemistry first investigated the theory of the best modes of its manufacture, and brought it to the highest state of perfection.

3296. *To the discoveries of Lavoisier, and the labours of his successors, we are indebted* for the clear and satisfactory basis on which the doctrine of fermentation is now established; and the names of Chaptal, Thenard, and Gay Lussac stand pre-eminent among those who have successfully studied this subject, and applied modern chemistry to the improvement of wine.

Among us, the writings of Dr. Henderson and Dr. Macculloch have contributed to diffuse scientific knowledge respecting wine; and, in his recent work, Mr. Redding has collected numerous interesting particulars. To these authors, among others, we willingly acknowledge our obligations.

SUBSECT. 2.—*Of the Grape-vine, and the Chemical Composition of the Grape.*

Wine, properly so called, is the produce of grapes only; and we refer the reader to some account of these in Book VII., Chap. IX., "On Fruits."

3297. *To make good wine, it is necessary that the grapes should have much saccharine matter*, and to produce this requires a great deal of solar influence; no other quality can compensate for the deficiency of sugar: hence the cultivation of the vine depends much upon climate.

The production of good wine from vineyards is limited to a zone extending in breadth from the thirty-third to the fifty-first degree of north latitude. Coblentz on the Rhine is the most northerly point; and Shiraz in Persia, and the Isle of Cyprus, the most southern. In the most northern parts of this zone the grapes are deficient in sugar, and the wines are often harsh and austere, like those of the Rhine and Mozelle; and in the southern part the grapes have a superabundance of sugar, and are deficient in other necessary principles; hence only sweet wines can be made there, or what are called *vins de liqueurs*, such as those of Malaga; in this part the grapes are often dried into raisins. The best wines are made in the centre of the zone, as those of Burgundy, Bourdeaux, and Oporto. But it appears that the ripening of fruits, particularly of the grape, does not depend altogether upon latitude; for a portion of the banks of the Rhine, where excellent wine is made, has the same latitude as the south of England, where it has been found very difficult to ripen the grape sufficiently in the open air, on account of the greater humidity and cloudiness of the atmosphere, which lessen the action of the sun's rays.

3298. *Grapes ripen best, and become sweeter, on a southern exposure*; and the sides of hills, with this aspect, are found to be the most favourable situations. On the banks of the Rhine, in the Apennines, in Hungary, and many other places, vines are planted in terraces formed on steep hills by means of low stone walls built along the sides; and into the cavities thus formed earth is conveyed: these walled terraces rise above each other, and thus form a kind of steps, like magnificent staircases, surrounding the hills.

The walls answer several purposes: by upholding the earth, they afford a soil for the roots of the vine, and they retain the water which flows down the hills, without, however, allowing it to stagnate; likewise, the reflection of the sun's rays from the sides of the hill increases the heat considerably, and causes it to accumulate on the vines: the walls are also convenient for fixing poles to train the vines upon.

3299. *The season likewise makes a difference in the quality of grapes.* In dry seasons the sugar will be more abundant, but the juice less in quantity; in wet seasons, on the contrary, the juice will be plentiful, but will contain much water and mucilage, with little sugar. Grapes, when quite green, are austere or styptic; next, they are acid, and become sweeter as they grow ripe.

3300. *The vine will grow in any soil that is not very wet,* but it flourishes most in one that is dry and light; and though it thrives with great luxuriance in rich soils, and produces abundance of grapes, yet this fruit is not so fit for wine as that which grows on poorer land. It is generally the case that the grapes fittest for the table are the least so for making wine, which is often obtained of good quality from fruit of a harsh and austere taste. It is generally thought that the best soil is one that is of a light calcareous or loamy nature; but even sandy, gravelly, and stony are found to answer well.

Volcanic soils are particularly well calculated for a vineyard; thus some of the best wines of Italy are made in the neighbourhood of Vesuvius, and the famous Tokay is also the produce of a volcanic district. The vine likewise grows well in the debris of granitic rocks, as is the case with that which produces the celebrated Hermitage. It appears even that the chemical composition of the soil is of less importance than its physical character. It has been observed that a black soil is particularly favourable from its absorbing heat.

3301. *The manner of training varies* in different countries. In Italy and other warm climates they are suffered to run up to a great height, and are trained on high trellises, or are allowed to spread with the utmost luxuriance, and to hang in festoons from tree to tree, the effect of which is described by travellers to be highly beautiful and picturesque. But in by far the greater part of Europe the vines are trained on low wooden props. The French and Germans, who excel in this branch of economy, prefer the low training, in which they cut the vines down to a few feet or less; and, although the fruit is diminished in quantity by this management, its quality is much improved by its obtaining more of the sun's heat through reflection from the ground. Those who have known vineyards only from the descriptions of poets are extremely disappointed in first viewing the stunted appearance of those in France and Germany. In the sandy parts of Spain the vines are even allowed to trail upon the ground. The modes of planting, propping, pruning, and renewing the vines have also a great influence on their produce in wine.

3302. *The varieties of the vine are innumerable,* differing in the size, colour, taste, and perfume of the fruit: of all fruits, perhaps none is so much altered in its nature and the proportion of its ingredients by the circumstances of climate and soil; no species of grape succeeding equally well in all climates. Good varieties degenerate by being transplanted from a warm to a cold climate; and, on the contrary, the grape is sometimes improved by being carried from a cold to a warm one.

The same climate, soil, and mode of culture often produce wines of very different qualities. Situation and aspect alone, all other circumstances being the same, make a very great difference. The same vineyard, for example, according as its different parts have a northern or southern aspect, will produce wines of opposite characters; as also will the same hill at its summit, middle, and bottom. In cold countries the southern slope of a rising ground is the most favourable situation, and in warm climates the east is found to be generally the best. Grapes form a very uncertain crop, and are much affected by wet seasons, hail-storms, and mists.

The principal varieties of grapes which are chiefly cultivated for foreign wines are the red and white Chasselas, or Muscadine; the Auvergnat; the Frontignac, or Muscat grape, white, red, and black; the Damask grape; the sweet water; the raisin grape; the malmsey grape; the malmsey Muscadine; the black Hamburg; but there are many more varieties, impossible here to enumerate. Wine-growers seldom confine themselves to one kind of grape, several being usually mixed together in the vintage; but in some choice wines only one sort is used.

3303. *The number and variety of wines* are almost infinite: every kingdom, every district, and sometimes each vineyard, producing a wine having some distinctive property, from which it receives a particular name. Thus we have the wines of Portugal, of France, and of the Rhine, each of a peculiar character; and the Tokay, Hock, and Constantia wines are each the produce of particular vineyards, their qualities depending on the varieties of the grape, as well as on several local circumstances, and the modes of manufacture.

Some have maintained that the vine ought not to be manured, when the production of wine is the object, from an idea that the manure affects the flavour of the wine: this opinion is maintained by many French wine-growers; and in the port-yielding district of the Alto Douro in Portugal, the use of manure is forbidden by law. But it is not clear that the practice of manuring is injurious; for in Germany, particularly on the Rhine, it is employed very freely: this is likewise the case in the vineyards near Bourdeaux, where the clarets are made. Liebig recommends the prunings of the vines themselves as the best manure. It is certain that the flavour of wine is affected by circumstances apparently inappreciable; scarcely two vintages afford exactly the same quality of wine, the vintage of some particular year, as that of the comet year of 1811, sometimes excelling all others.

3304. *Grapes differ considerably in their constituents from other materials employed for fermentation.* The juice of the grape not only contains a larger proportion of saccharine matter than that of other fruits, and is consequently capable of producing a greater quantity of alcohol, making a stronger liquor; but it differs also in the nature of its acid, which is chiefly the tartaric, that being almost the only acidulous principle existing in it, particularly the mature grape ripened in a warm climate, such as Spain, Portugal, or Madeira.

3305. *The abundance of tartaric acid in the grape is one of the principal causes of its excellence as a material for wine.* Other fruits employed for this purpose, as gooseberries, currants, elderberries, &c., contain chiefly the malic, citric, and acetic acids, which are partly combined with potash, forming malate and citrate of potash, and partly in a free state; but these salts, being soluble both in water and in alcohol, necessarily remain in the wine that has been prepared from the fruits, nor can they be separated; hence all the wines made from other fruits, except the grape, contain a quantity, generally considerable, of free acid, which is injurious, at least to certain constitutions; and as the acids are not palatable, they are usually concealed by a large quantity of saccharine matter, as we shall afterward find when the processes of making these wines are described.

The tartaric acid, on the contrary, does not exist in the grape in a free state; but it is always combined with potash, constituting bitartrate of potash; and this is the substance known by the name of *tartar.* This tartar is most abundant in the juice of unripe grapes, called often *verjuice*, and has an austere taste; it lessens in quantity as the grape approaches to maturity, when the sugar increases in the same proportion.

The tartar is held constantly in solution in the grape juice; but as soon as the fermentation commences, and alcohol is evolved, a portion of the tartar is precipitated, or thrown down in the solid form, because it cannot be kept in solution by alcohol; and the latter has diminished to a certain degree the solvent power of the must. The precipitation of the tartar takes place upon the bottom and sides of the containing vessel, to which it adheres as a hard crust in a crystalline state, called the *lees* of the wine. A small quantity of tartrate of lime is also found united to it, and exists even in the purified tartar, or common cream of tartar; hence it follows that, if the grapes are of the best quality, containing tartar, they have but little or no free acids; and if the fermentation has been well conducted and complete, the resulting wine will be quite, or almost entirely, free from acid of any kind; and it is this circumstance chiefly that renders the grape superior to every other fruit for producing a wholesome wine. But wine is never perfect until it has subsequently undergone the *very slow fermentation*, which brings it to its highest point of perfection, when a still farther quantity of the tartar subsides, and constitutes what is called the *crust* when bottled, the quantity of which usually gives an idea of the quality and age of the wine.

All grapes, however, are not entirely without other acids besides the tartaric; but they seldom contain any of these in considerable quantity, and in that case they are less fit for the production of good wine.

Besides the essential principles of the grape, namely, sugar, tartar, and natural ferment, it contains some mucilage, and an aromatic essential oil in minute quantity, to which the delicate perfume or aroma of the wine made from it is owing.

3306. *The vintage should never commence before* the grapes have arrived at their full maturity, except in cold countries, where sometimes the season is so late before they can be ripe that there is danger of their spoiling if they are not quite ripe; yet brisk wines can be made from them. In the manufacture of the best wines, they are careful to avoid the two extremes of gathering the grapes not sufficiently ripened, or so ripe that they begin to spoil. In warm countries, in the manufacture of sweet luscious wines, the grapes are permitted to hang on the tree till they shrivel, or they are gathered and half dried in the sun.

3307. *When they are to be collected,* a sufficient number of persons are employed, so as to be able in a single day to gather all that is necessary to fill the fermenting vat. The unripe or decayed fruit should be carefully separated, a circumstance which is often neglected in manufacturing the inferior wines, and in the fabrication of wine for distilling into brandy. In making Champagne, however, they prefer having a certain proportion of unripe fruit. For the rich sweet wines, the juice is concentrated by leaving the grapes exposed to the sun for a few days; but, in general, the fruit is taken at once to the press. In the richer and best wines also, where a very delicate flavour is expected, all the stalks are removed; but in the strong, rough wines a certain proportion of the stalks are kept, as they give strength and astringency. In the preparation of port wine they are always used; but in the manufacture of the more delicate wines of Bordeaux they are generally excluded. The practice of different countries differs much in this respect, and in weak wines they are apt to communicate a harsh and austere flavour.

3308. *The bruising the fruit*, or *pressing*, is performed in various ways in different countries, according to the care bestowed in the manufacture. In many parts of France, the grapes are put into tubs with perforated bottoms, and men tread them with their *sabots*, or wooden shoes, the juice running out into the vat or tub placed below. This mode is imperfect; and where the vintage is conducted in the best manner, presses are made use of for this purpose, by which the process is performed more uniformly and completely. The skins and refuse, after the grapes have been pressed, constitute what is called the *marc*.

3309. But before we proceed to describe the manufacture of wine we must explain the principles upon which its formation depends.

Subsect. 3.—*Sketch of the Theory or general Principles of Wine-making.*

The theory and process of fermentation having been already treated of at some length in Book VIII., Chap. II., we shall confine ourselves here to a concise recapitulation of those particulars respecting it which are requisite towards a connected view of wine-making.

3310. *It was observed that when any sweet vegetable juice, whether a decoction of malt, juice of the grape*, or that of other fruit, is exposed to the ordinary temperature of summer, say from 50° to 70°, it soon begins to exhibit that intestine motion termed fermentation, and distinguished by the production of alcohol, which remains in the liquid, and of carbonic acid, which chiefly escapes in the form of gas.

3311. If a decoction of malt be fermented, the produce is *ale* or *beer;* but if grapes or other sweet fruits have been employed, *wine* is the result.

3312. It has been shown that the process of fermentation depends essentially upon the presence of two substances at least: saccharine matter, and another vegetable principle termed a leaven or ferment, the nature of which appears to be extremely analogous to, if not identical with, gluten or vegetable albumen. These two substances, which exist more or less in all sweet vegetable juices, act upon each other, and occasion a decomposition into their elementary principles; and when these unite again in other proportions, they give rise to the two essential products of fermentation above mentioned, alcohol and carbonic acid. The phenomena of fermentation and the liquid resulting from it vary in some degree according to the relative proportions of the saccharine matter and the ferment.

3313. *When the juice of the grapes*, or *must*, as it is termed, is put into the vat, at a temperature of 60°, it soon begins to ferment spontaneously: no yeast is added, as in the case of beer or ale, because the natural ferment contained in grapes is sufficient to excite and keep up a sufficient fermentation. We may mention it as remarkable, that although expressed juice ferments so readily, yet this process never takes place in the juice before the fruit is bruised. The fact is, the sugar and the ferment are contained in different parts of the grape, and they never come into contact except the fruit is broken.

The general phenomena of fermentation have been so particularly described when treating on that subject at large, and again under "Brewing," that we shall not detain the reader by repeating it in detail. The appearance of air bubbles, and of a gentle ebullition, together with the turbid state of the fluid, are the same in all cases: a portion of the exhausted ferment, now rendered insoluble, rises to the surface with another portion not exhausted, constituting the yeast, the remainder falling to the bottom in the form of lees. The gas which escapes is known to be the carbonic acid.

3314. *In the ordinary methods of making wines there are two periods in the fermentation. The first or primary fermentation in the vat* is the most considerable, in which the principal part of the sugar and ferment are decomposed; and, of course, alcohol produced. After this first effort of the fermentative process, the usual phenomena disappear, and the effects sensibly diminish; the process should now be stopped, otherwise the liquor would advance to the acetous state of fermentation. While this fermentation was proceeding, yeast being thrown up, and tartar and mucilage precipitated, the liquor had become muddy; but as the fermentation lessens, and these impurities have gradually subsided to the bottom as lees, the new fluid, or wine, becomes clearer, and the vinous taste is perceivable. But though the operation has apparently ceased, it has not in reality; and it mus be continued longer before the wine becomes perfect. It is said that the fermentation is most perfect where large quantities of must are operated upon. Lately, it has become the custom to increase the fermentation, when it is required, by the addition of *starch sugar*, which is of the same kind as that of the grape.

3315. *After the first fermentation has continued for a sufficient time*, according to the kind of wine to be made, it is then racked off or transferred to casks to suffer a slow fermentation, generally termed, not very correctly, the *insensible fermentation;* but care must be taken not to pour off the lees which have settled to the bottom, nor the yeast on the top.

When first put into the casks, the wine still contains a portion of fermentable matter, which, though not sufficient to produce the very visible effects of ordinary fermentation, is yet sufficient to occasion a slower state of this process, which continues a longer or a shorter time, according to circumstances.

During this second fermentation in the casks, the wine becomes turbid, and there is a slight internal motion in the fluid ; yeast is thrown off by the bung, and the casks are kept always full, that it may pass out upon forming. The management of this second fermentation must depend upon various circumstances, chiefly the kind of wine to be manufactured.

3316. *When the fermentation in the casks has continued till the wine is properly depurated* by throwing off the yeast, the bungs are driven in tight, and the wine is left to deposite its tartar, which it does in consequence of an extremely slow fermentation, which often continues for a long time, during which the wine is ameliorated by a more intimate combination of the alcohol with the acid and mucilage; this frequently requires several years in the wood.

3317. *Another effect of this prolonged insensible fermentation* is the gradual increase of the quantity of alcohol, and the farther separation of the insoluble salt, the bitartrate of potash, called *tartar*, which subsides, adhering to and lining the bottom and sides of the casks as lees. As the taste of tartar is harsh and disagreeable, it is evident that the wine will be improved by being deprived of it, and hence old wine is preferable to new. There is, however, sometimes a danger in putting the liquor into the casks before it has had sufficient time to ferment in the vat. If the unfermented matter is in too large a quantity, it will ferment violently in the casks and become turbid, and, if it be put into bottles, will probably break them. Again, if the fermentation has been carried too far, there is a chance of the liquid souring and turning to vinegar.

A portion of the colouring matter, as well as tartar, is also precipitated, adhering to the sides of the cask ; the wine is mellowed, and the aroma and flavour that are peculiar to it become more apparent. These changes are sometimes accelerated by various artificial means, especially by the agitation of the lees, which always contain a portion of the ferment, and by the assistance of artificial heat. Hence the reason why certain strong and austere wines are so much improved and mellowed by being exported in the lees to a warm climate, as is the case in carrying Madeira to the West Indies, or in subjecting it to the effect of local motion of any kind with heat, as is now practised in the island of Madeira. On the contrary, the lighter and more delicate wines are injured by the motion even of removal to any distance, and, therefore, can be drunk in perfection only in the countries where they are grown.

3318. *To prevent this renewal of the fermentation*, therefore, after a certain time, when most of the lees has been thrown down, and it is thought the wine has acquired a sufficient degree of maturity, it is poured off into a clean cask, which process is technically called *racking*, which is a method of transferring the fluid without disturbing the sediment.

3319. After this, should there appear to be any risk of the fermentation beginning again, a process is employed called *sulphuring*, which consists in burning sulphur matches within the cask ; the sulphurous acid gas thus produced is absorbed by the wine, and this has the effect of stopping the fermentation. In some places this latter process is varied by strongly impregnating a small quantity of wine with this gas, which they then call *stum* wine, which they put into the cask for the same purpose.

3320. Sometimes, after these operations are finished, the wine is not completely clear, and requires to be *clarified* or *fined* by isinglass, whites of egg, or substances of that kind. Finally, the whole is completed by bottling.

3321. *The fermentative process, as well as every part of the manufacture of wine, requires great attention* united to experience and skill, and it varies exceedingly in different places ; so that, although the subject has received considerable elucidation and improvement from the labours of Chaptal and other eminent chemists, particularly in France, where, perhaps, the best wine-makers in the world are to be found, yet the French themselves allow that there is still much to be done before fixed rules can be given ; and our object here is rather to touch upon the prominent facts in the manufacture of foreign wines than to enter into minute details.

Subsect. 4.—*Distinctions in Wine which arise chiefly out of the Manufacture.*

3322. *Perhaps the most obvious division of wines* is according to colours, as *red* and *white*; but another arrangement, generally received, considers them as, 1, *dry and strong*, as Port, Sherry, and Madeira ; 2, *dry and light*, as Hermitage, Claret, Burgundy, or Hock ; 3, *brisk, effervescing, and sparkling*, as Champagne ; 4, *sweet*, as Malmsey, &c. ; to which we may add the *Vino cotto*, or boiled wines.

To understand well these distinctions, it is necessary that we attend to some circumstances in the manufacture which give rise to them.

3323. *The colour of wine is owing to the following causes :* If the skins of the grapes or marc are entirely excluded from the fermenting vat, a *white wine* is always obtained, the juice of almost all grapes, black and red, as well as green, being colourless. Champagne is made from a red grape so deep in colour as to approach to black, and sherry is made from a mixture of white and coloured grapes. The colour of *red wine* is derived from permitting the wine to ferment in contact with some of the marc, the colouring matter of the grape residing altogether in the skin, with the exception of the grape called *Tintilla*, from which Tent wine is made, in which the juice is coloured. This colouring principle is soluble in alcohol; therefore, when the alcohol is developed by the fermentative process, the must becomes coloured in consequence of the action of the spirit upon the marc. The wine is also more deeply coloured, from a higher degree of pressure given to the husks of the grapes. The colour of red wines varies from a light pink to a deep purple tint, approaching to black; the clarets hold the intermediate rank between these two extremes; and Dr. Henderson observes that, "on exposing red wine in bottles to the action of the sun's rays, the colouring matter is separated in large flakes, without altering the flavour of the wine." The colour derived from the skins of the grapes alone is not generally very deep; and the high-coloured wines of France and Portugal are often rendered so by colouring ingredients, particularly by mixture with an intensely deep-red wine called *vino tinto*, and sometimes by elderberries and colouring drugs.

Part of this colouring matter is often precipitated by long keeping in the bottle, as is the case with port; and hence one of the tests of the age of port that has been kept in the cellar is the paleness of its colour, though this is sometimes produced fraudulently. Some white wines are nearly colourless, but the greater portion have a yellow tinge; and the pale yellow wines, when long kept, acquire more or less of a bright amber hue, and sometimes a tinge of brown. Certain wines, as those of Moldavia, have even a greenish colour.

3324. *Agreeable flavours are occasionally given to wine* that do not belong to the grape by means of aromatic substances, such as orris-root, elder flowers, raspberries, &c. The nutty flavour of some Madeira wines is given by almonds. The ancients relished the flavour of resin or pitch in their wines, a taste which continues among the modern Greeks, but would be intolerable in this country.

3325. *The distinction of dry, brisk, and sweet wines* depends upon the mode of conducting the fermentation. To explain this part of our subject, we must recall to the reader's recollection a few of the leading facts respecting this process.

We stated that the formation of alcohol, which constitutes the distinctive property of every vinous fluid, was the result of the mutual action of saccharine matter and the fermenting principle on each other; and that wine consists of a combination of this alcohol, water, a minute quantity of the essential oil of the grape constituting the peculiar aroma, and sometimes colouring and astringent matter.

3326. *Dry wines* are those where the saccharine matter and the ferment were so exactly balanced that they have decomposed each other by their mutual action, and no sweetness is perceptible, a certain quantity of sugar requiring a certain proportion of ferment for its decomposition. This is considered to be the most perfect class of wines, as the best Burgundies and ports. Such perfectly fermented wine is free from acid, and is not liable to change in any moderate length of time.

3327. *Sweet wines* are those where the saccharine matter was in too large quantity to be decomposed entirely by the ferment, or where the process of fermentation was interrupted before its completion; consequently, some of the sugar remained unacted upon, and in a free state in solution in the wine. Of this class are the rich malmsey and Muscadine wines, as Malaga, &c. In making sweet wines, boiling the juice is sometimes resorted to, because by the heat a part of the ferment is coagulated and rendered ineffective; and, therefore, the whole of the grape-sugar is not decomposed during fermentation, owing to the deficiency of this principle. If the grape-juice be deficient in sugar, some cane-sugar is added, or, what is better, starch-sugar, which is the same as that of the grape.

3328. *Brisk or effervescing wines* have had the fermentation checked before it was completed, the wine being transferred into bottles before the whole of the carbonic acid had separated, a portion of which, being formed by the continuance of fermentation in the bottle, is there absorbed by the wine, and retained in a condensed state; this, when freed by withdrawing the cork, is disengaged with noise and violence, giving the appearance described by the term briskness, such as is seen in the common Champagne.

From the above description, we may see that it is easy from the same grape juice to make any of the three classes of wine, by certain management in the manufacture, for which more particular directions will be given when we treat of the making of domestic wines.

3329. *What is termed the bouquet of wines* is that agreeable aromatic odour which is perceived on drawing the cork of any of the finer wines on their exposure to the air. In some of the Burgundies and other French wines, it is highly rich, and does not seem like a single perfume, but rather as the union of several. This aroma, so much valued in some wines, cannot be accurately described by words, and must act upon the senses to be comprehended. It appears to depend upon a fugacious principle, probably some extremely volatile oil, which the chemist has not yet been able to separate, perhaps from the quantity being too minute. In the sweet and half-fermented white wines, this is immediately derived from the fruit, as in those from the Frontignan and Muscat grapes; but in the more perfect red wines, as in claret, Hermitage, Rivesaltes, and Burgundy, it bears no resemblance to the natural flavour of the grapes from which they are made, and is altogether the product of the vinous process. This delicate aroma, when it exists, considerably enhances the quality and value of the first wines, and it is dissipated and lost by too rapid a fermentation. Liebig has lately described this volatile substance, the produce of the fermentation, as a peculiar ether, which he has named *œnanthic ether.*

The wines of warm climates have no odour; those of France have it in a considerable degree, but the perfume is the most intense in the best Rhenish wines.

3330. *The flavour of wines*, called by the French *sève*, is different from the *bouquet;* the former indicates the vinous power and aromatic savour which are felt in the act of swallowing the wine, whereas the latter affects the organ of smell rather than that of taste. In the red wines of Medoc and the Graves, these, the sève and bouquet, are developed only in the old wines. A fictitious bouquet is sometimes given to new wines by means of orris root.

3331. *It is not an uncommon thing for the manufacturers of wine to mix two or more wines together*, in order to produce one of better quality, by correcting the defects of each other. By this mixing, the fermentative process is partially renewed, and the mixture is said to *fret;* hence the practice is called *fretting in.* Mixed wines appear to unite into one durable and homogeneous liquor only in consequence of this kind of fermentation.

3332. *Boiled Wines*, or *Vino Cotto.*—In our account of the wines of the ancients (Sect. II., Subsect. 11) we shall find that it was their practice to concentrate the must by boiling; thus increasing the relative quantity of sugar and fermenting principle by reducing the water. This method is still followed in some parts of Europe, as in Greece, Italy, and Spain. The richest grapes of the Muscadine species are chosen for this purpose; and after having been exposed for a few days to the sun, they are pressed in the usual manner, and the juice boiled till it is reduced to one third. It is then skimmed and put into vessels to cool, after which it is barrelled up. These wines are very pleasant to the taste, of a deep amber colour, delicate and generous. Mr. Redding states that Corsica is famous for such wines, which are treated so judiciously by boiling, that in the north of Europe they are taken for Malaga or Canary. When very old, they are often passed off for Cyprus, Tinto, or Malaga of the best kind, as the owner may wish them to seem. But many boiled wines, as they experience very little fermentation, scarcely deserve the name of wines, and are little more than boiled must; of this kind are several varieties of the *vino cotto* of Italy, particularly near Bologna.

Sect. II.—DESCRIPTION OF FOREIGN WINES.

3333. It is not our object to attempt the complete description of the vast number of wines produced in various parts of the world; we shall confine ourselves to such as are imported into Britain, or have acquired such celebrity as to be pretty generally known among us. This subject may be considered as so much the more important, since immense sums are annually expended in the purchase of foreign wines, yet an accurate knowledge respecting the true merit and value of the various kinds is little diffused, and money is sometimes injudiciously expended on this class of luxuries. It will be most convenient to treat of the wines of various countries separately.

Subsect. 1.—*French Wines.*

3334. France, owing to her fine climate, and the great fertility and variety of her soil, is eminently calculated for the manufacture of wine. In that country, also, scientific principles have been applied to it with great success. Not only is wine produced in France in the greatest abundance, but likewise in the greatest variety, from the light Champagne and Burgundy to the luscious sweet winds of the south, and the *vins ordinaires* of the several districts.

3335. But notwithstanding the celebrity of French wines, which are transported to every part of the world, and the acknowledged skill of the manufacturers, it must not be supposed that they are to be indiscriminately approved of. A large proportion of French wines is of a very inferior character, and it is only from the first establishments that the finest wines are to be procured.

Although in France there are only a few departments in which the vine is not cultivated, yet certain wine districts have acquired greater celebrity than others, either on account of the superiority of their produce, or from their being more conveniently situated for exportation.

Those departments which compose the ancient provinces of Champagne, Burgundy, and the Bordelais at present furnish the greatest abundance of the best French wines. Some of the sweet wines of the southern departments are excellent; but the wines of the northern parts of the kingdom, as those of the Moselle, are, in general, very indifferent.

3336. *It is generally supposed, in England, that French wines are too cold for the constitution*, and particularly for those who have been accustomed to port and sherry. There is probably some truth in the observation, when the ordinary French wines are taken into the account; but the objection will not apply to the stronger wines of that country, even when they are quite free from brandy. It is observed by Dr. Henderson that France furnishes some of the best wines in each class, and unquestionably excels every other region of the globe in the manufacture of red wines in particular.

3337. *During the period when England had possession of several provinces of France*, French wines were imported into this country in great abundance from Gascony, Guienne, Touraine, Anjou, and Poitou; and in the beginning of the reign of Henry II., a considerable trade in wine with Bordeaux commenced; but the Gascon wines exceeded in quantity all the others. It would appear, from the large quantities imported, and the low price at which they were obliged, by royal enactments, to be sold, that foreign wines must have been pretty generally drunk in England at that time among the wealthy classes. The province of Guienne remained in our possession near three hundred years. Richard II. was born in Bordeaux, the capital, while it belonged to England; and the province was given up only in the reign of Henry VI. So cheap were French wines in England in the reign of Henry VIII., that those of Gascony and Guienne were forbidden to be sold at above eightpence the gallon.

The wine trade with France was in the most flourishing condition under Edward III., when, as Froissart relates, upon one occasion a fleet of above two hundred merchantmen came for wines from England to Bordeaux, then the seat of the Black Prince's government. In the same age the wines of the Rhine and Moselle appear to have been largely imported. It was upon Gascony that the English chiefly depended for their favourite supplies of clarets and other light wines, which seem to have resembled generally the modern growths of the same country.

3338. *Champagne Wines.*—This, the most celebrated of French wines, is the produce chiefly of the province of that name, and is generally understood, in England, to be a brisk, effervescing, or sparkling white wine, of a very fine flavour; but this is only one of the varieties of this class. There is both red and white Champagne, and each of these may be either still or brisk. There are the sparkling wines (*mousseux*), and the still wines (*non-mousseux*). The brisk are, in general, the most highly esteemed, or, at least, are the most popular in this country, on account of their delicate flavour, and the agreeable pungency which they derive from the carbonic acid they contain, and to which they owe their briskness.

There is a great difference in the quality of these wines, according to the particular vineyards at which they have been made. The finest wines are produced in the sloping grounds on the north bank of the River Marne, where the soil is extremely calcareous; and they are mostly white wines.

3339. The very finest of the sparkling Champagne is that of *Ay*, five miles south of Rheims; its delicious aroma has been compared to that of the pineapple. This place has long been highly distinguished, and our ancestors took no small pains to secure to themselves the choicest productions of the vineyard; for it is said that Francis I. of France, Pope Leo X., Charles V. of Spain, and Henry VIII. of England, had, each of them, a vineyard at Ay, their own property, and on each vineyard a small house occupied by a superintendent. *Sillery* is a white Champagne, and the best of the still kind; it has more body and spirit than the sparkling varieties, and is very highly esteemed. This wine derives its name from the Marquis of Sillery, the original proprietor of the soil, and is produced from vineyards not far from Rheims; it is, perhaps, the wholesomest of all the wines of Champagne, the fermentation being more perfect. It will keep for years, whereas the sparkling wines soon spoil. Almost the whole of it goes to Paris and England.

The red Champagnes are seldom brought to England; but a few of them rival the rich wines of Burgundy. That of Clos de St. Thierry, near Rheims, is of a quality between Burgundy and Champagne, and is very highly prized by the connoisseur. There are also rose-coloured Champagnes; but these are less in request.

In selecting Champagne wines, many consider the briskness and effervescence as a test of their excellence; but a good judge will prefer a liquor of moderate briskness, as the aroma evaporates with the froth. Champagne is best to be iced a little before it is used, which tends to repress the effervescence, though, when it is kept cool, this is unnecessary.

The manufacture of Champagne in the best manner requires considerable skill, and is a matter of difficulty and uncertainty: it is always bottled; and the breakage is generally so great as to amount to from 10 to 20 per cent. loss. Cellars of immense size are cut in the chalk of the district where it is chiefly made, in which the temperature is very equable.

3340. Champagne intoxicates speedily, probably in consequence of the large quantity of carbonic acid which it contains, and of its alcohol being in a very volatile state; the excitement produced by it is of a more lively and agreeable character than that which is occasioned by any other kind of wine; but its duration is shorter, and the exhaustion which follows is less.

Dr. Henderson remarks that the general opinion of its being apt to occasion gout is at variance with the fact that this complaint is very unfrequent in the district where it is made, but he likewise observes that it is prejudicial to those habits which are liable to gout from other causes.

The price of Champagne in France varies considerably, according to the scarcity or abundance of the crop. On an average, the best Champagne is sold to the dealer at 3 francs a bottle. Transportation to Paris and the Octroi bring the price to about 3½ *francs*; and at the restaurateur's it costs 6 francs.

3341. *Burgundy—Vins de Bourgogne.* The choicest wines of the ancient province of Burgundy are certainly the first in the world for richness of flavour, perfume, and fulness of body, although they are not so popular in England as Champagne. These wines are both red and white. The red is most highly esteemed; but the most exquisite of these are so delicate they can scarcely bear exportation, though, like Champagne, they are always bottled; and, to have them in perfection, they must be drunk in the country where they are made. What we call Burgundy in England is seldom of higher quality than the second or third rate wines. The best of these wines are produced in so small quantity, and are so much in request in France, that they fetch there very high prices, and do not answer much more than the home demand; consequently, a very small proportion comes into our market.

The finest Burgundies are produced in the department of Cote d'Or, in Upper Burgundy, and a great deal is made round the town of Beaume. There is rarely more than one kind of grape grown in this part, namely, that called *noirons*, the colour of which is black when ripe, and quite round. From Beaume the best wine can be procured; it is sent in bottles above ninety miles to Auxerre, whence they pass, by means of the rivers Yonne and Seine, to Paris, and then down the Seine to Havre and London.

The first in quality of these wines is the Romanée Conté, but it is seldom met with genuine out of France. Next is the Chambertin, which, it is said, was the favourite wine of Louis XIV., as also of Bonaparte. The Clos Vaugeot is inferior, but more abundant. There are many other excellent wines of this class, scarcely known in England, and others are of an inferior description: hence our wine merchants, who are not such good judges of their quality as the French, are very liable to be imposed upon in purchasing them. In the second class of red Burgundies are the Maçon wines, also Chambolle, Muscigny, and Volney.

The white wines of Burgundy are less excellent, and in smaller number than the red, but still some of them rank very high for their fine flavour, particularly the Mont Rachet, La Perriere, La Goutte d'Or, Les Charmes, and Chablis; these are not dear, yet are little known in England.

3342. *Bordeaux Wines.*—All those wines called in England *clarets* are the produce of the country round Bordeaux, or the Bordelais; but it is remarkable that there is no pure wine in France known by the name of claret, which is a corruption of *clairet*, a term that is applied there to any red or rose-coloured wine. Round Bordeaux are produced a number of wines of the first quality, which pass under the name simply of *vin de Bordeaux*, or have the designation of the particular district where they are made, as Lafitte, Latour, &c. The clarets brought to the English market are, in general, prepared for it by the wine-growers by mixing together several Bordeaux wines, or by adding to them a portion of some other wines; but in France, the pure wines are carefully preserved distinct. The genuine wines of Bordeaux are of great variety, that part being one of the most distinguished in France; and the principal vineyards are those of Medoc, Palus, Graves, and Blanche, the produce of each having characters considerably different.

The red Medoc wines are of the very first quality, and are known by the designations of Lafitte, Latour, Chateaux Margaux, &c. When in perfection, they possess a rich, red colour, a bouquet resembling the perfume of violets and raspberries, are very agreeable, and are strong without readily intoxicating. The Lafitte is reckoned to have the finest flavour. The Margaux wine is next in rank. The Latour is the strongest of the Medoc wines, having the fullest body, but wanting the great softness of the others; it is, however, the principal one brought to the English market.

The Medoc district consists of a large plain lying on the north of the city of Bordeaux, and situated between the River Gironde and the seacoast of the Bay of Biscay. The vines grow on hills, consisting of a light, sandy, and calcareous loam, intermingled with flint pebbles. The quantity of the best wines made annually does not exceed eighty tons, far too little to supply all the places pretending to sell them; what is usually bought is, therefore, at least, of the second quality. So rare are the first-rate wines, that a bottle of the best Lafitte, Chateaux Margaux, or Haut Brion, costs, even in Bordeaux, six or seven francs. Some of the vineyards of the Lafitte have lately been purchased by an English house. Medoc wines of the second and third rate qualities are Leoville, Poulliac, Rauzan, &c. All the Medoc wines bear a sea voyage, and are rather improved by it.

3343. *The vins de Graves* are so called from the gravelly soil on which they are produced, to the east and west of Bordeaux: they are both red and white, but the latter is most celebrated and best known in England. Some of the red approach to the flavour of Burgundy, though inferior to the first of the Medoc wines.

Another class of white Bordeaux wines, well known in England, consists of Barsac, Sauterne, Beaume, &c., which have the advantage of keeping long and having considerable dryness.

The Palus wines are inferior to those of Medoc. They are strong and rough when new, and are often employed to mix with Medoc wines, to give them strength and body; but some of them, when old, have a rich bouquet. It is stated by Mr. Redding that there is a particular manufacture known by the title of *Travail à l'Anglaise* for preparing claret for the English market; in this, to each hogshead of pure Medoc wine is added three or four gallons of Spanish wine of Alicant or Benecarlo wine, half a gallon of stum wine, and sometimes half a gallon of Hermitage, which is of a very superior quality. This mixture undergoes a slight fermentation, called fretting in, and is then exported as claret. It is fortunate if this escapes being mixed with brandy. But the French wine brokers at Bordeaux, familiar with the qualities of the first growths, and anxious for the reputation of their wines, will supply claret with no other addition than Hermitage, providing a proper price be given.

The Bordeaux wines, when genuine, may be considered as among the most perfect which France produces. The fermentation, in general, being more complete than in any other, they are much less disposed to acidity and other disorders than the wines of Burgundy; they have less aroma and spirit, but more astringency, in consequence of which they are considered as the safest for daily use. The wines of Basseins and St. Eulalie d'Ambarres, near Bordeaux, furnish a wine that is generally purchased for the French navy, because it keeps well, and improves greatly at sea.

Besides the wines of the Bordelais which we have mentioned, there is a prodigious number of second and third rate wines made in this district, many of the latter unknown here by name, and seldom sent out of the country. Notwithstanding the late act by which the duties on French and Portuguese wines are equalized, and much reduced, yet Mr. M'Culloch, in his "Dictionary of Commerce," considers that the wine trade will not be placed upon a fair footing till the duty is imposed on an *ad valorem* principle. At present the same duty is paid on an inferior and cheap wine as on the choicest Burgundy and Champagne; and the effect of this is to exclude all low-priced wines from the English market. Bordeaux is, commercially speaking, nearer to London than to Paris; and, were it not for this system, the cheap wines of the Gironde, Languedoc, and Provence might be bought at a less price in England than in most parts of France, as was the case some centuries ago. Mr. Porter states, in his "Progress of the Nation," that there are good light wines produced in France that could be imported at sixpence per bottle without the duty, which is at present about one shilling per bottle.

3344. *Various other French Wines.*—Besides those wines of which we have given a short description, and which are best known in England, France produces a multitude of others, in almost every department, of various degrees of merit, and which it would far exceed our limits to specify. The celebrated *Hermitage* is the produce of vineyards situated on a hill of decomposing granite on the Rhone, twelve miles from Valence, in Dauphiny. It derives its name from some hermitages, now in ruins, to be seen upon the rock. The hill is so steep that the vines are planted on terraces, and the exposure is to the south. Red Hermitage is distinguished by its full body, deep purplish red, being the richest in colour of all French wines, and of an exquisite flavour and perfume resembling that of the raspberry. There is also a white Hermitage, which is considered as the finest white wine produced in France; its odour is like no other wine; its taste is rich, dry, and luscious. Of the wines grown in the Lyonnais, on the Rhone, the most noted is *Cote Rotie*, which bears a near resemblance to Hermitage, and is remarkable for the excellence of its colour, strength, and perfume.

As the climate becomes warmer near the shores of the Mediterranean, the vines grow with greater luxuriance, and many of the red wines of Languedoc and Roussillon are extremely fine, and of great body. Much of these strong wines of the south are sent to Bourdeaux to mingle with the poorer wines, to make up those for exportation.

3345. Some of the red wines of Roussillon are nearly of the strength and flavour of those of Oporto without brandy, and have been brought to England at two thirds of the price. A few years back some good Roussillon wine was imported and sold under the name of *Masdeu*: it is difficult now to get it here of the same quality; and it is said that most of it is carried to Oporto and shipped there as port, being thus charged at double or treble the price it ought to be.

3346. It is here also that those luscious sweet wines called *muscatel* are made of Muscadine grapes, such as those of Frontignan, Lunel, Rivesaltes, &c. The latter affords, perhaps, the finest Muscadine wine known.

The white wine called *Chablis* is grown at the village of Chablis, about two miles from Auxerre.

3347. All the vineyards between Fontainebleau and Paris are on the southern sides of the hills, which always furnish the best situations for vineyards. The Parisian wine-merchants, when they wish to have genuine wine, take care to secure it before it gets into the hands of the country merchants, who mix it with their old stock, or with the strong wines of the south, to make *more Burgundy*. This practice explains how almost all the inns in France pretend to have the choicest wines, notwithstanding the smallness of the quantities of each actually grown.

SUBSECT. 2.—*Wines of Germany, Hungary, and Switzerland.*

3348. The parts of Germany where good wines are produced are more limited than those of France. Those imported into England are chiefly from the banks of the Rhine.

3349. *Rhenish Wines.*—The choicest vintages of that country are confined to a small district called the *Rhingau*, on the right bank of the Rhine, including a space of little more than nine miles in length and four in breadth, from Basle to Mentz. The banks of the river there present favourable soils or exposures, being confined between high and steep banks, extremely suitable for the grapes, which are raised in terraces, and yield a profusion of excellent wines. North of Coblentz the wines are of little comparative note.

The first of the Rhenish wines for fine flavour and absence of acidity is the *Johannisberg*, produced on the south side of a hill of that name, a little below Mentz, which was originally planted by the monks of the abbey of Johannisberg. The choicest of all is called Schloss-Johannisberg, from a vineyard at the castle formerly belonging to the Bishop of Fulda, and now the property of Prince Metternich. Little of this comes into the market, and its superiority to the other wines of Johannisberg is accounted for by the care bestowed on the cultivation of the grape. But other vineyards in Johannisberg give wines of the first class.

The produce of the *Steinberger* vineyard is considered by some as next in rank, and is the property of the Grand-duke of Nassau. It is strong, with much sweetness and delicacy of flavour. It sells on the spot for eleven shillings a bottle. *Rudesheim* and *Graefenberg* are also among the first of these wines. Of second quality, are those of Marcobrunner, Roth, Konisbuch, &c. The true *Hock* is so called from the vineyards of Hockheim, a little town, not on the Rhine, but on the Mayne, a few miles from its junction with the former river; but this is always classed with the Rhenish wines, being nearly of the same excellence. Indeed, not only the wines made near Hockheim receive, in general, the name of Hock with us, but likewise, generally, those of the Rhine, the Mayne, the Nahe, and even the Moselle.

3350. The wines of the Rhine form a class different from all other wines. Some of the lighter kinds bear a considerable resemblance to the vins de Graves; but they are, in general, drier than any French wines. They are generous, finely flavoured, and are characterized by a delicate aroma that is peculiar to them. Though they do not contain much alcohol, yet, from the completeness of their fermentation, they will keep longer (continuing to improve by age) than the potent wines of the south with double the alcoholic strength. From a peculiar tartness which they possess, it is generally thought in England that these wines are acid; and the inferior kinds, no doubt, are so to a certain degree; but Dr. Henderson and others observe that this is by no means the constant character of Rhenish wines, many of which, in good years, have not any perceptible acidity to the taste; at least, not more than is common to them with the growths of warmer regions. It would appear, from their dryness and brightness, that the saccharine matter and the leaven have completely acted upon each other, and that the latter is all precipitated. Dr. Henderson is of opinion that they owe their durability to this circumstance, and to a considerable proportion of tartar, which they retain for a long time, the greater part of which is at length precipitated. In bad seasons, however, there is no doubt but that the inferior wines contain a portion of malic acid, in consequence of the grapes not having arrived at a state of full maturity.

The most celebrated of these wines are fermented in casks, by which the fine aroma is preserved, and then, after being repeatedly racked, are kept for years in very large vessels to mellow. Every one has heard of the tun of Heidelberg, which held six hundred hogsheads, and other prodigious vessels of that kind, in which wine has been kept even for centuries; and it is necessary that these should be always full, more new wine being added when any is drawn off, which, it is thought, contributes to their durability. For the more delicate wines, however, smaller vessels are preferable. It was, until lately, the custom in Germany to bury earthen vessels filled with wine at the birth of every child, not to be taken up till its marriage. Old Hock, though generous and durable, is considered as less heating, and, at the same time, more exhilarating than many other wines.

3351. *The Moselle wines* have, within the last few years, become very fashionable in England, and, when iced in the summer, are extremely grateful. They have a great analogy with those of the Rhine, and are generally classed with them, though inferior. The most celebrated are the Brauneberger, Wehlen, &c. Some of the good Moselle wines are cheap, and may be imported into England at three shillings a bottle.

Franconia and Suabia supply some white wines, which often pass for those of the Rhine; but in Austria the wines are very inferior, and extremely acid. The red wines of Germany are not of a superior kind, and have nothing to recommend them.

3352. *Hungarian Wines.*—The good wines of Hungary are limited to a few districts, although there are abundance of vineyards in the kingdom. By far the most celebrated of the Hungarian wines is Tokay.

3353. Dr. Bright informs us, in his "Travels in Hungary," that it "is raised in the last chain of the Carpathian Hills, in the neighbourhood of the town of Tokay. The district containing many vineyards extends over a space of about twenty English miles. Throughout the whole of this country it is the custom not to collect the grapes till they have become dry and sweet, like rasins, while hanging on the trees. They are gathered one by one; and it is from them alone that the prime Tokay, or, as it is termed, Tokay Ausbruch, is prepared, which in 1807 sold for 100 florins the cask of 180 halbes on the spot. They are first put together in a cask, in the bottom of which holes are bored to let that portion of the juice escape which will run from them without any pressure. This, which is called Tokay essence, is a sirupy liquor, and generally in very small quantity, and very highly prized. The grapes are then put into a vat, and trampled with the bare feet, no greater pressure being permitted. To the squeezed mass is next added an equal quantity of good wine, and the mixture is allowed to stand for twenty-four hours to ferment, and is then strained. The juice, without farther preparation, becomes the far-famed wine of Tokay, which is difficult to be obtained, and sells in Vienna at the rate of £12 per dozen. The greater of these vineyards is the property of the emperor; several, however, are in the hands of the nobles."

3354. The Vignerones prepare the grapes while on the vine in the same manner as the Italians do theirs for their famous Lacryma Christi: they go every morning through the vine rows, and give each bunch of grapes arrived at maturity a twist, and hang it over an adjoining branch of the vine, that the twist may not come out. This partially interrupts the ascent of the sap from the roots, and occasions them to dry, yet without wholly cutting off the sap, as this would cause them to dry too quickly, and concentrate the juice so that it would not flow on a moderate pressure. There are four kinds of wine made from the same grapes, Essence, Ausbruch, Masslach, and common wine, or vin du pays. The essence is thick, and seldom perfectly clear, very sweet and luscious; it is chiefly used to make up the other kinds, and when mixed with the masslach, forms a wine equally good with the ausbruch, and often sold for it. The principal ausbruch wine, of which presents are made to foreign ambassadors, and which is drunk at royal tables, is made up with essence.

3355. Another species of Hungarian wine, called *meneser*, is said to equal Tokay; next to that in value come the wines of Œdenburg, Rusth, St. Gyorgy, and Ofen, followed by a great many others, whose names are as various as the hills which produce them. It is interesting to remark that all these wines are produced upon soils originally volcanic. The vines are kept cut down close to the ground. Dr. Henderson well remarks that the Tokay essence corresponds exactly to the sirupy wines of the ancient Romans, and that the Tokay ausbruch, a dry, sweet wine, appears much the same with their wine called *passum.* But Dr. Townson, who travelled into Hungary, notwithstanding the encomiums passed upon Tokay, is of opinion that much of it does not surpass many of the sweet wines of Spain. Cracow in Poland is the chief deposit of old Tokay, and it has been sold as high as eight ducats a bottle. Hitherto the Hungarian wines have been little known in England, from the difficulty of transportation; but the improvements now making in the navigation of the Danube may probably be the means of introducing them in greater abundance into the British market.

3356. The Buda wine is very like Burgundy, and perhaps equal to some of it. It is said to have been a favourite wine at the court of London in the reign of James I. The Sexard wine on the Danube, between Buda and Esset, is strong and deep-coloured, cheap, and of good quality. These wines may be imported by the way of Trieste.

3357. *Swiss Wines.*—Switzerland produces some good wines, but they are not exported. Red wines are made at Schaffhausen, Bode, and Erlach in Berne: that of Neufchatel resembles Burgundy. In the Valteline they have an excellent red wine, much resembling those of France. Fine red wine is made in the country of the Grisons, and one which is white, called Chiavenna. In Valais they make some good wines, but others are very indifferent. The canton of Vaud produces dry wines resembling Rhenish.

Subsect. 3.—*Wines of Portugal.*

3358. From the climate of Portugal, one might expect its wines to be excellent; yet great part of the red wine imported from that country under the name of *port* is well known to be of a very inferior quality. It will be useful to trace the cause of this.

3359. Before the revolution in 1688, great quantities of French wine were imported into England, to the extent some years of 20,000 tuns. Besides Portugal, Spain and Italy at that time came in for a considerable share of our wine trade; and Spanish wines were imported from Gallicia, Alicant, Malaga, Barcelona, Benecarlo, and other places; Italy supplied us from Leghorn and Florence.

3360. When the war with France broke out in 1689, England was deprived of the supplies of Bordeaux claret, which, previous to that time, had been the wine chiefly drunk in this country. Recourse was had, as a substitute, chiefly to the red wine of Portugal, which then appears to have been imported for the first time, but which has ever since been the principal wine used in England, so as to have even changed the public taste in a remarkable manner.

In addition to this cause of difficulty in procuring French wine, the British government imposed a *discriminating* duty of £8 a tun upon it, and in 1697 raised it to no less than £33 a tun—a blow, it is said, then aimed at the French nation, in consequence of Louis XIV. having espoused the cause of the exiled family of Stuart.

It is very probable that this excess of duty would have been repealed when the excitement which gave rise to it had subsided, had it not been confirmed by the famous commercial treaty in 1703 with Portugal, which was negotiated by Mr. Paul Methuen, hence called the Methuen treaty, through which we bound ourselves to charge one third higher duties on the wines of France imported into England than on those of Portugal, the Portuguese, by way of compensation, binding themselves to admit our woollens into their markets in preference to those of other countries, at a fixed and invariable rate of duty. This, at the time, was considered as highly advantageous to this country, not considering that by this vindictive policy we gave the Portuguese a complete monopoly of the British market, at the same time that we excluded one of the principal equivalents which the French had to offer for our commodities, and thus deprived ourselves of commerce that would have been far more extensive than that with Portugal, besides provoking France to a retaliation that has been injurious to both parties.

The high duties thus imposed upon the wines of France became almost prohibitive, while the comparative cheapness of the wines of Portugal afforded a strong motive for their introduction. Previously to this time there were few vineyards on the banks of the Douro, and the wines sent to England were chiefly those of Lisbon or the adjacent country. But the increased demand for Portuguese wine led to the extension of vineyards. Several British supercargoes had settled at Oporto, and it is said that they first encouraged the proprietors of lands in the Upper Douro to devote themselves to the cultivation of the vine. But as the demand for the wines of that territory continued to increase, and the produce of the new vineyards were necessarily often of inferior quality, the growers and dealers resorted to various expedients for supplying the deficiency in the quantity required for exportation.

Originally the Portuguese wines were sent to England pure and unmixed with brandy, but soon after this treaty was concluded the Portuguese began to adulterate their wines, mingling brandy with the must during the fermentation, either from an impression that it was necessary to make them keep for exportation, or from some other causes less excusable. It is said, also, that an English factor, who resided at Viana, near Oporto, discovered and taught the use of the elderberry in deepening the colour of their wines. At that time Florence wine, which is highly coloured, being much drunk in England, a deep-red colour was thought necessary for the English taste; and hence, no doubt, have followed numerous expedients for giving artificial colour to wine.

About the middle of the last century, this practice and other adulterations became so prevalent that a considerable diminution took place in the consumption of Portuguese wine, and the trade of the growers, consequently, suffered in proportion. Many complaints of the adulterations of the wine were made, even by the English merchants themselves settled at Oporto; and some of these, in conjunction with the proprietors of the vineyards near Oporto, succeeded, through the influence of the Marquis of Pombal, in obtaining, in 1756, a charter from the Portuguese government to sanction a joint-stock company, with the avowed object of securing the reputation of the wines of the district by preventing all adulteration, and to protect the commerce. This charter granted to the Oporto Company the monopoly of a certain extent of territory on the River Douro, in which Oporto is situated, in which alone all wine intended for exportation was permitted to be raised; but, in fact, these vineyards were those belonging to the monasteries and the principal gentry of the country; and the absolute disposal of these wines was placed in the hands of the company, who were allowed to fix the prices to be paid for them to the cultivator, and likewise that for which they were to be sold to the foreigner; all mixture of these wines with others without the boundary being prohibited, however useful that might have been to the quality of the wines.

By this a complete monopoly was obtained by the Oporto Company, as far as England was concerned, of the best wines of Portugal. Some of the reasons for granting such a charter, such as checking the adulteration, were sufficiently plausible; but the injurious effect of this monopoly, and the injudicious conduct of the company, has been a subject of severe animadversion; and it has been confidently stated by almost all writers respecting it, that they have eventually been the means of retarding the improvement of the wines of Portugal instead of ameliorating them.

In Portugal, although the climate, soil, and situation are eminently well calculated for the growth of the grape, yet its cultivation is, in general, unskilfully managed, except in a few places: of these the principal are the vicinity of Lisbon and Oporto.

The wine country, or district of the Cima de Douro, or Upper Douro, granted to the Oporto Company, and from which we have our port, commences about fifty miles from Oporto. The wines produced here, the whole of which were purchased by the company, were divided into those destined for exportation to the English market, together with those consumed in Portugal, and such as were used by the distillers of brandy, and for supplying the taverns in Oporto the latter are seldom mixed with brandy. Wine that is the pure growth of the Douro, unsophisticated by any admixture of brandy, and that has not passed through the hands of the Oporto Company, is of a full mellow body, great mildness, and exquisite flavour; but the best of this wine is scarcely known in England. The very first growth of the Upper Douro is said to be produced at Pezo da Regna, and, when not brandied, resembles some of the Rhone growths of France, or the Cote Rotie. It has been frequently asserted, and is generally believed, that such wines will not bear sea carriage, or that they will not keep any length of time, without a certain portion of brandy, and also that the quality of the wine is much improved by this admixture. Whether this practice was originally begun in consequence of such opinion, or merely to please the English taste, cannot easily be determined; but it is maintained by Dr. Macculloch, Dr. Henderson, and others who have paid most attention to the subject, that brandy is not at all necessary to the preservation of wine that has been properly manufactured, and that, if mixed with wine, it never completely incorporates with it.

Dr. Henderson remarks that, "if the saccharine principle has been fully decomposed, and the superabundant leaven carefully separated by sulphuring and other means—or if a greater proportion of sugar exist in the must than the ferment can possibly decompose—the wine produced may be kept in close vessels, without any risk of alteration, during a long term of years." But he observes that in wines imperfectly made, and inclining to acescency, the change may be retarded by brandy. But, in checking one evil, another is brought on; "for it is very certain that, when the addition is made after the full fermentation of the must, no perfect incorporation of the two fluids will take place; but the flavour and perfume of the wine will become completely obscured; and the adventitious alcohol, combining with the aqueous part of the liquor, will occasion a gradual separation of the extractive and colouring matter, leaving merely a mixture of brandy and water with a slight vinous tinge. That this is the case must, I think, be evident to every one who has observed the progress of the decomposition incident to the inferior port wines, which can never be said to be in condition, but which, after a certain period, lose what little flavour they possessed, and become more or less tawny, while lighter wines, that contain no adventitious spirit, remain quite unchanged." This addition of brandy explains one of the methods by which many fraudulent wine-merchants produce the deposition of the crust on the sides of the bottle, which is supposed to indicate the years the wine has been bottled.

The power given originally to the Oporto Company, of fixing the price of the wine purchased from the grower, had a pernicious influence upon the quality of the wines of the Douro. They were usually fixed, by a fiat of their own, to two rates of prices, one for the wine for exportation, and another for that for home consumption; and they paid the cultivators the same price for these two kinds, whatever was their quality. To save the trouble of tasting the produce of each farmer, and paying him in proportion to its value, the whole of the small quantities was put together into one batch or repository for exportation, in order that they might be enabled to supply their customers in England with wine of the same or a standard quality; and, after the wines had been purchased of the great farmers, the agents bought up small quantities, even if inferior, to mix with the rest. The largest vineyards belonged to the monasteries, and the Jesuits were the best skilled in the making of wine. An acre of vineyard yields about three or four pipes. The wine growers had, therefore, no motive to exert superior skill and ingenuity, but contented themselves with raising, at the least possible expense, the greatest supply of such wine as was required for exportation, for which the company gave the highest price. All emulation was thus effectually extinguished; and the proprietors who possessed vineyards of a superior quality invariably mixed their wines with inferior growths, so as to reduce them to the port standard, and increase the quantity of average wine. "In this way," says Dr. Henderson, "the finer products of the Douro vintages have remained, in a great measure, unknown to us; and port wine has come to be considered as a single liquor, if we may use the expression, of nearly uniform flavour and strength, varying, it is true, to a certain extent in quality, but still always approaching to a definite standard, and admitting of few degrees of excellence. The manipulations, the admixtures, in one word, the *adulterations*, to which the best of the wines of the Cima de Douro are subjected, have much the same effect as if all the growths of Burgundy were to be mingled in one immense vat, and sent into the world as the only true Burgundian wine. The delicious produce of Romanée, Chambertin, and the Clos Vougeot would disappear, and in their place we should find nothing better than a second-rate Beaume or Macon wine."

Not only, however, did the Oporto Company deteriorate the quality of their wine, but they also raised the price to an enormous height. In the year 1755 a pipe of red port might have been bought in the wine country, at the first hand, for from 2*l.* to 3*l.* per pipe; but, on the first setting up of the wine company, they raised the price to 8*l.* or 10*l.* per pipe. As the charter granted to the Oporto Company gave the sole privilege of exporting the wines of the Douro, they were secured against all competition from other English merchants, notwithstanding the Methuen treaty; and enjoying a complete monopoly of the British market, in consequence of the high duties on French wines, they filled their pockets at our expense; and at the time, says Fleetwood Williams, when they were shipping wine for England at 40*l.* a pipe, they have frequently sent the same quality of wine to other countries at 20*l.*!

The late alterations in the duties on wine, by which those on French and Portuguese wines are equalized (all wines now paying 5*s.* 6*d.* a gallon except Cape), will, no doubt, do much to repair the evils which have been complained of. The Oporto Company has undergone considerable modification, and many of its obnoxious privileges have been abolished. It remains to be seen how far these changes will improve the wines we have been describing. At present, since the injurious effects of brandied wines begins to be understood, intelligent port-wine merchants have endeavoured to bring over port wine with as small an admixture of brandy as possible; and, as taste improves, there is no doubt but that the genuine flavour of pure wine will be preferred to the fiery compound that is yet so general.

3261. *There are upward of forty varieties of the vine cultivated in Portugal;* but the most common or general sort used for the fabrication of port wines is called there the *Uvo Bastardo,* or bastard grape. It is of the smallest sort, round, about the size of an English sloe, grows quite close in the cluster, and has a remarkably thick, tough skin. In some seasons the skin is thicker than in others, and when it is thickest the wine is deepest coloured, and most astringent. The juice itself is colourless, and the deep red of the wine and its astringency are owing to the husks and stalks of the grapes during fermentation.

3362. *At present* we are informed that the farmers in the wine countries of the Douro, and also the merchants, are in the constant habit of mixing their wines, and giving to them those colours and flavours which render them acceptable to the consumers in the foreign markets where they are sold. This they make no secret of, the flavouring and colouring ingredients being thrown out of doors when the useful part has been extracted; nor do they consider this as an abuse, but as a part of the manufacture, in the same manner as with us, the distiller compounds his spirits for cordials. But most, if not all, the substances so employed are harmless, and it is only after the wine gets into the hands of fraudulent dealers that it receives noxious ingredients. Port, while in the wine country, is often coloured, when it is pale, by vino de tinto, or even by elderberries; thin-bodied varieties are blended with full and rich-bodied wines, to bring the whole to the market standard, and are strengthened by old Benecarlos wine of Spain, or the red Roussillon of France.

When the wine arrives in this country from Oporto, it is of a dark purple or inky colour, has a full, rough body, with an astringent and rather sweet taste, and a strong flavour and odour of brandy. After it has remained some time longer in the wood, the sweetness, roughness, and astringency of the flavour abate; but it is only after it has been kept also several years in bottle that the odour of the brandy is completely subdued, and what remains of the genuine aroma of the wine is developed. During the process of melioration, a considerable portion of the extractive and colouring matter is precipitated on the sides of the vessel in the form of *crust.* In some wines this change occurs much earlier than in others, particularly in those which have been manufactured with white grapes and coloured with elderberries.

3363. Several of the other vines of Portugal, although they do not find their way to this country, are described as excellent, plentiful, and as equal, if not superior, to those of the Douro. Among these are the growths of Torres Vedras, Monçaon, and Lunego. In general, these lighter red wines resemble the secondary growths of the Bordelais, and are inferior to port. A red wine called Colares Port, grown near Cintra, is sometimes imported into England. Tolerable red wines are also occasionally shipped at the ports of Viana and Figuerra, from which England used to be supplied previous to the introduction of the Oporto wines.

3364. The *vino tinto,* which has been mentioned above, is a thick, sweetish, black-red wine, formerly, and even at present, much used in deepening the colour of the red wines of Portugal, and seldom drunk alone; it is made from the wild vine, commonly called the *claret grape.*

Some excellent white wines are likewise produced in Portugal. *Bucelles,* grown a few miles above Lisbon, when pure, is much like *Barsac;* but, when it comes to us, is much brandied. *Carcavellos* and *Setuval* are sweet wines from the province of Estremadura, and known in England by the name of *Lisbon,* because they are shipped at that place; the first receives its name from the village of Carcavellos, near the rock of Lisbon; it is richer and dearer than common Lisbon, which is a pleasant-tasted wine, formerly much used as a table wine.

3365. *White port,* now little known, much resembling red port, except in colour, is the produce of the red and white grapes of the Douro, expressed together, and prepared in a similar manner to the red port, except that the marc, or skins and foot-stalks of the grapes are not fermented with the must. It is a wholesome, not unpleasant wine, mostly drunk in the country where it is made, or distilled into brandy.

Subsect. 4.—*Spanish Wines.*

3366. Spain, from the warmth of its climate and excellent soils, has many advantages for the manufacture of wine. The red wines are in general much inferior to those of France; but the Spaniards excel in the preparation of dry white wines, particularly of the sweet kinds, which are great favourites in Spain, and were formerly so in England. The vast abundance of wine in that kingdom, and the facility with which it is everywhere obtained, renders the inhabitants careless about the means of preserving it, and the wines are usually kept and carried about in goat's skins smeared with tar or pitch, which communicates a taste often so unpleasant that they are scarcely drinkable by strangers. Casks and bottles are very little used, partly through the poverty of the people, and because skins are more easily transported by mules on bad roads. The hole by which the original owner of the skin was taken out is sewed up; so are the legs, which serve as handles to carry it by, with the exception of one, which is tied by a string, and is used as a spout to draw off the liquor. The universal use of these skins (called *bota*) in Spain is one of the first things to attract the attention of a stranger, and gave rise to one of the most diverting adventures in the Don Quixote of Cervantes. Cellars are scarcely known, except in monasteries and large towns; but in the houses of the better classes, where the wines are kept in wood, they are often found of excellent quality.

3367. The finest wines are made in Andalusia and Granada, where great care is bestowed on the cultivation of the vine, and it is in the former province that the wine known among us by the name of *sherry* is produced. The term sherry is a corruption of *Xeres*, being made at Xeres de la Frontera, a few miles from Cadiz. The wine district is here six square leagues, and about 17,000 pipes are exported annually. Many of the principal vineyards in Xeres are in the hands of British and French settlers, whose agents superintend the manufacture of the wines. The grapes, which are white, are left to hang in the sun till they are partly shrivelled, and are exposed to it for forty-eight hours after they are gathered; at the same time, some quicklime is thrown over them, for the purpose of mollifying the fruit by neutralizing the acid, lessening the coarseness of the skin, and rendering the extraction of the juice easier and more abundant. After the grapes have lain a sufficient time they are put into a press, and there some brandy is sprinkled over them. The juice being extracted from the marc, brandy is again added, and the must goes through a regular fermentation; it is afterward put into casks and racked, when, again, another addition of brandy is made.

3368. *Wine-merchants distinguish several kinds of sherry*, as pale and brown, and there are various degrees of each.

Sherry, in general, is of an amber colour, and when good it has a fine aromatic odour, with something of the agreeable bitterness of the peach kernel. When new, it is harsh and fiery, and requires to be mellowed in the wood for four or five years. The wine-merchants of Xeres never exhaust their stock of finest and oldest wine, but keep it for adding a portion to what they dispose of at the highest price.

Sherry has of late got much into fashion in England, from the idea that it is more free from acid than other wines; but some careful experiments on wines do not fully confirm this opinion, and it is found that the *best* Madeira and port are equally free from acid. Two dry sherries are highly esteemed in Spain, *Amintillado* and *Manzanilla*, and they are said to be entirely devoid of brandy, and equally free from acid; but they are seldom brought to this country, though they deserve to be. The Amintillado, when genuine and old, fetches a high price, and is sometimes added to improve the ordinary sherries by its nutty flavour.

Pale sherries are made from the same grapes as the brown: the latter are coloured by an addition of some cheap must or wine which has been boiled till it has acquired a deep brown tint. The pale sherries were, some time ago, preferred in England, being supposed more pure; but the brown are now getting most into fashion. The inferior sherries exported to England are often mixed with a cheap and light wine called *Moguer*, and are strengthened in the making by brandy; but too frequently they receive adulteration by the London dealers. It is even asserted by Dr. Macculloch that a third of all the so-called sherries consumed in England is the produce of the home presses!

3369. The fine climate of Granada renders the vintage in that province extremely abundant as well as certain, furnishing the Muscatel, Bloom, and Laxias raisins.

The hills round Malaga are covered with vines, and no less than 10,000 presses are said to be at work during the vintage. The most celebrated of the wines are white, but there is also a sweet red wine called Tinto de Rota, so called from Rota, a little town opposite Cadiz, which produces but little true Tinto, and that is principally consumed in the country; this is what is called, among us, *tent* wine: it is a rich wine, used as a stomachic, and made from a deep red grape.

The wines of Malaga, known among us by the name of *Mountain*, are of two kinds, sweet and dry. The sweet wines are made from grapes completely ripe, and, when genuine, are highly esteemed; the dry wines are from grapes not so mature, are of an agreeable flavour, and improve by age. Some of the Malaga sherry comes next to that of Xeres, and is cheaper.

From Valentia, the *Benicarlo*, a strong, full-bodied, deep-coloured red wine, is exported chiefly to Bordeaux, as we have stated, to mingle with the wines of that place, in making up the claret for England, and to Oporto, for mixing with port. It is grown at a place which is a few miles from Valentia. At Alicante they have an excellent red wine.

From Catalonia a great deal of red wine is annually shipped to Bordeaux, and sent to England. The Macabeo of Catalonia is a sweet white wine; but the wine of this province is chiefly remarkable for its strength.

La Mancha is a wine district. There the celebrated Val de Pinas is produced: it is a good red wine, like unadulterated port. As it is sold at about 3*l*. 10*s*. per pipe, Mr. Inglis, a late traveller, observes that an enterprising merchant, taking with him into that country wine staves just before vintage, might secure, at an easy price, some very excellent wine. Murcia produces some very good *vins de liqueurs.*

3370. It is stated, in a late Spanish journal, that in consequence of the abundance of the growth of oranges in the south of Spain, several of the growers prepare from them a delicious wine, resembling Madeira in its flavour: the juice is fermented and put into casks, without the addition of brandy.

3371. Besides these Spanish wines, there are many in the various provinces little known to us; and there is no doubt but that, as the kingdom improves, they will one day be in much higher estimation, and will encroach much upon the Portuguese and French wines. When to the happy nature of the climate, and the richness of the soil, are superadded peace, knowledge, and industry, Spain may probably rival every country in its wines, although at present it is chiefly famous for sweet and white wines.

SUBSECT. 5.—*Wines of Madeira and the Azores.*

3372. The Island of Madeira is almost entirely of volcanic origin, and the soil produced by decomposing lava is found to be very favourable to the growth of the vine. This, added to the warmth of its climate, renders this place celebrated for the excellence of its wines. The vine was planted there soon after its first settlement by the Portuguese in 1421; but the introduction of the wines of Madeira into England is of more modern date than those of Portugal, and they were first brought here about the middle of the last century from the West Indies, which had been supplied from the island where they are made.

3373. *Madeira produces several kinds of wine.* The finest is *Sercial,* a red wine obtained from a grape much like the Malvasia, but which will only succeed on certain spots. The quantity of this wine produced does not exceed forty or fifty pipes in the year; it is harsh and austere when new, but is mellowed by being kept long.

3374. *The white wine usually known in England by the name of Madeira* is made in the greatest proportion; and, when genuine, is one of the richest wines in the world, having great strength, dryness, and delicacy of flavour. It is extremely durable in all climates, and is improved by age. It is meliorated in a remarkable manner by a sea voyage, a circumstance which was observed when it was first exported to North America. In consequence of this improvement, it has been the custom to prepare it for the European markets by sending it purposely to the East and West Indies, which, of course, must very considerably enhance the price. But it is by no means the case that the wine which has been on a voyage to India is the best Madeira, for inferior wines have been sometimes supplied for this speculation; and it has been discovered lately that by keeping the wine in a certain warm temperature, particularly with agitation, it is nearly as much improved as by a sea voyage, and in a much shorter time. Accordingly, it is the practice at present to ripen the wine in stoves in the island, where it is kept in a heat of 90°.

Madeira, being a strong wine naturally, has, least of all, occasion for the addition of brandy; yet it is the constant practice to add some of this spirit previous to exportation, which time incorporates. In other respects the first sorts are very little sophisticated; but the inferior kinds, of which there is a large proportion, are made up with almonds and various additions.

3375. The English wine-merchants who reside in Madeira consign their wines to agents in London, from whom it may be had genuine; and there is no other way of getting it good; but the great demand of late is said to have exhausted the island of all the finest old wine. Madeira should not be kept in a cold under-ground cellar, but in a warm part of a dwelling-house. To have it in perfection, it should be kept several years in wood, and nearly as much in bottle.

3376. *A Malmsey* wine of the first quality is also produced in Madeira from the Malvasia grapes, which are kept till over-ripe and partly shrivelled by hanging a month longer than the other grapes. This wine was much in request in England before the use of tea, when a few glasses were drunk after a meat breakfast: it is now little imported.

3377. Part of the red grapes are employed in making a wine called *tinta,* which is extremely astringent, and, when new, resembles Burgundy; but when it has been kept some time, it becomes pale, like tawny port, or even paler, and acquires, in part, a rich Madeira flavour.

3378. All the best wines are grown on the south side of the Island of Madeira; those from the north side are very inferior, and are chiefly used for distilling brandy, which is not very good; these are too often exported instead of the best wines; and they alone, well brandied, are sent to Russia. But even on the south side the wines are not all of the same quality; about one half is inferior to the rest, but are usually passed off as some of the best.

Madeira wines have lately got much out of fashion, and the prejudice against them has been considerably increased by a supposed discovery that they contain a little more acid than sherry, which is now generally preferred; but this opinion is disputed, having been derived from the inferior Madeiras. So difficult is it to distinguish all these varieties of wine, that a large portion of the inferior Madeiras are now sold for sherry; and even the best Cape wine passes for Madeira. It is stated in Holman's Travels that the winet rade of Madeira is rapidly declining; and that, in consequence, the planting of coffee has become very general in the island.

3379. The *Azores* produce a Malmsey, called *vino passado*, and also a dry wine; but both are inferior to Madeira wines.

3380. *The Canary Islands* formerly produced a great deal of sweet wine, which was formerly imported into England.

3381. *Teneriffe* has the best wines of all these islands: what is called Vidonia is a dry wine, much resembling Madeira. The Malmsey of Teneriffe is excellent: common Teneriffe wine is inferior. The wines of these islands were formerly, in England, called *Sack*, as well as sherry and Malaga. Orotavia is a wine so called from the port where it is shipped.

SUBSECT. 6.—*Wines of Italy, Sicily, and Greece.*

3382. Before our intimate connexion with Portugal in the wine trade, some wines were brought from Italy and Greece, but at present very little is imported from thence. Notwithstanding the favourable soil and climate of these countries, the wines produced there, with a very few exceptions, are of an inferior quality.

3383. The wines of Italy are all made for home consumption only; and though many good wines are produced by land proprietors for their own use, the greater part of the ordinary wines are execrably bad, principally owing to the careless mode in which they are manufactured. In Tuscany, however, more attention has been paid both to the cultivation of the vines and to the vintage than in the other Italian states, which is much owing to the care of the grand-dukes. In the villas of Italian noblemen some good wines may be found, but these are not exported. The sweet Muscadine wine of Monte Pulciano is the most celebrated, and the red Muscadine of Aleatico; but the Tuscan wines, upon the whole, do not equal those of Spain and Portugal.

3384. The volcanic soils round Naples are particularly favourable for the vine; and the exquisite Lachryma Christi, produced on Vesuvius, is well known; but the best variety of red wine grown at Galetta, having a rich Muscadine flavour and perfume, is very rare: an inferior kind is sold from Torre del Greco, and other places in the vicinity; a white Muscadine is also made on Vesuvius. A bottle of full-bodied wine of the ordinary kind may be had at Naples for twopence halfpenny, and at Rome for fourpence.

3385. Calabria produces some good wines; but in some parts the heat is even too great, and they are obliged to shade the vines from the sun.

3386. The principal wines of Italy are consumed in Rome, and some very fine are made in the Papal States, as at Albano, Monte Fiascone, and Orvietto, &c.; but they do not bear carriage, and are known only in the country.

3387. Throughout Italy, generally, the vines are suffered to run up in wild luxuriance, being carried from tree to tree round the enclosures, without any pruning, and to waste their strength, not in fruit, but in leaves and branches. In fact, such a quantity of fruit is produced with very little trouble, that the farmers, who use the wine only for their own beverage, and have no motive sufficiently powerful to induce them to take much pains, manage the vintage in the most slovenly manner. The wines are, therefore, often exposed to acidity.

3388. *Sicily* is nearly in the same circumstances as Italy with respect to the abundance of its wine, and the bad management of it in general. The Marzara and Marsala white wines are imported into England; and, could they be had free from the admixture of Sicilian brandy, which is peculiarly harsh, would be found of good body, and to resemble the lighter kinds of Madeira. They are among the least expensive of our foreign wines; and many of the vineyards are in the occupation of English merchants. Some of the hills at the foot of Mount Etna are covered with vineyards, and a great variety of wines are produced there; but it is only the inferior growths that are brought to us. Some red wines are made, but they are not excellent.

3389. *Corsica* produces, among several wines of various qualities, one called *particolore*, of excellent flavour, and a fine red colour: it is stomachic.

3390. *Greece, so celebrated in ancient times for its wines*, still produces some of superior quality, and in many places the processes of manufacture are far from being injudicious.

3391. Before the oppression of the Turks, good wine continued long to be made in Candia, Cyprus, Scio, Tenedos, Cephalonia, Zante, Lesbos, Nanos, and Santorini. When under the Venetian republic, Candia and Cyprus supplied the whole of Europe, and particularly Venice, with the finest Malmsey, and towards the end of the sixteenth century they exported 200,000 casks of this wine. Since the conquest of Greece by the Turks the quality of the wines has deteriorated; but Candia and Cyprus at present afford an excellent red wine resembling claret, and dry as well as sweet muscadine white wines of a very fine quality; in short, these two islands alone could furnish us with every variety of wine in abundance. Wine of Cyprus is particularly praised for its keeping quality, and improving by age: in that island, the hills on which the vine is cultivated are covered with stones or flints with a blackish earth. The vessels in which the grape-juice is fermented are of earthen-ware, covered internally with a mixture of turpentine and pitch, and the art of making them is extremely ancient; the leathern bags in which the wine is carried are pitched, which communicates to the wine a taste which does not go off for many years; it is ten years old before it is exported. Mr. Fuller informs us that the chief production of Cyprus now is wine, of which there are several qualities; the red kinds are sound and well flavoured; but the most celebrated is the white wine, called *vino della commanderia* (from its having been originally made on vineyards belonging to the knights of St. John), which resembles in taste the *vino d'oro* of Mount Lebanon, or the Mountain of our cellars: it is exceedingly strong, and will keep and continue to improve till a very great age. The muscadine wine of Cyprus is excessively sweet, and drinks best at two years of age; it has probably undergone no change since the days of Strabo and Pliny, who considered it as the most valuable in the world; after sixty or seventy years this wine is as thick as sirup.

3392. But in many parts of Greece, where circumstances do not admit of the proper means being employed in making and preserving the wines, and where the poverty of the inhabitants prevents their having casks, they are spoiled by the pitch and tar which the skins to hold them are smeared with; and a custom prevails of adding to them salt, gypsum, and lime, with a portion of resin, as among the ancient Greeks. These mixtures are not drinkable except by the inhabitants.

3393. *In the Ionian Islands*, now in our possession, some excellent wines are made. Those of Cephalonia and Ithaca have been found very fine, the former having a peculiar muscadine flavour. In Zante there are both dry and sweet wines. Corfu produces *Rosolio*, a rich liqueur wine; others resemble claret. These wines are now beginning to be drunk by some of the Turkish magnates, notwithstanding their prohibition by the Koran. In some of the islands they use vats of masonry, and some keep the wine in large earthen jars, which they bury up to the neck in the ground, in the manner of the ancients.

Malmsey is a corruption of Malvasia, from Napoli de Malvasia in the Morea, where that class of sweet wines was originally made, and which has since been imitated in every wine country in the world. The conquest of that country by the Turks destroyed this manufacture in the Morea; but it is still continued in Candia. The term is now applied to any wines of the sweet and luscious kind.

3394. *On the Crimea* some good red wines are produced; and, as the climate is excellent, and the Russians are very desirous of wines and brandy, the cultivation of the vine is on the increase.

SUBSECT. 7.—*Wines of Africa.*

3395. The Mohammedan religion has impeded the cultivation of the vine in Northern Africa, although wine is made in a few places by Jews and others not Mohammedan, as at Tituan, where it is said to equal that of Xeres.

3396. *Cape Wines.*—At the Cape of Good Hope, the goodness of the climate and the equality of the temperature are particularly favourable to the cultivation of the vine; and large quantities of wine are now brought to us from thence. The Dutch were the original settlers at the Cape, and first planted vines there in 1650. But they have been extremely imprudent in their choice of situations for the vineyards, many of them being placed in rich, low soils, instead of being confined to dry, rocky lands; and their mode of culture proves that they were more solicitous about the quantity than the quality of their wine. To this defect has been added careless training and dressing; in consequence of which, with a few exceptions, the wines of the Cape are at present of very inferior quality. These exceptions, however, prove that good wine may be produced in that country. The grapes originally planted were the Muscadine, Frontignan, and other European varieties; and in those parts where the soil has been congenial, and the mode of culture proper, good wine is manufactured. The best wine of the Cape is *Constantia*, so called from being made on two farms of that name, and about eight or nine miles from Cape Town, where the soil is stony. One farm produces red wine, and the other white. Very good wine is also produced in some other places. There is also a white wine called *Cape Hock*, and a red wine called *Rota*.

Cape Madeira is said to be mixed with some boiled must; but it is likewise strengthened by bad brandy. Most of the Cape wines brought to England have a disagreeable taste called *earthy*, are often acid, and want flavour; yet the smaller duty which they pay occasions the importation of an immense quantity; that annually entered for home consumption being about 540,000 imperial gallons, much of which is said to be employed as a convenient menstruum for adulterating sherry, Madeira, and other wines.

In no other wine country is there greater room for improvement in the manufacture of wine, nor is there any place where science and care, properly directed, would produce more beneficial results. As the Cape is the only colony which we possess where the art of manufacturing wine is practised upon the great scale, it would appear to be extremely desirable that the new settlers should be made acquainted with those scientific principles which have given the French so great advantage.

SUBSECT. 8.—*Wines of Asia and America.*

3397. It does not enter into our plan to follow up this sketch of an account of the principal wines of Europe, by noticing all those in the other quarters of the globe, yet it would seem imperfect were these entirely omitted.

3398. *Persia* is supposed by some to have been the native country of the vine, and certainly it grows there with unequalled luxuriance, the grapes attaining an extraordinary size. The Persians have always been less scrupulous observers of the precept of the Koran, which forbids the use of wine, than other Mussulmans; many of them indulge freely in this beverage, and suppose that they evade the law by drinking only what is made by Jews or Armenians. The white wine of Shiraz has a high celebrity, and a great deal of it is sent to the East Indies in bottles. A fine, sweetish, red wine is made near Ispahan. These are the only wines at present made in Persia.

Some wine is made in the *Crimea* belonging to Russia. In 1831, no less than 9,600,000 bottles of red wine, called Kokour, were produced in that province.

3399. *The other wines of Asia* are few and little known. Syria produces red and white wines like Bordeaux, and boiled wines are made on Mount Libanus. India produces little or no wines, except in the northern parts, near the Sutledge and Indus. At Lahore good wine is made, and also in Candahar and Cashmere; the latter resembles Madeira. Grape wine is scarcely known in China.

3400. *Wine is made both in North and South America*, in many places. In the former the vine grows wild on the Ohio, and also in Louisiana and Florida, where the grapes attain an immense size, and wine is made, but not of the best quality. The Hock grape was introduced into Canada and Ohio by German settlers. Near Washington is grown a species of grape named *Catawba*, unknown in Europe; and at Boston there is a good grape called *Isabella*. South America abounds in vineyards. Between Buenos Ayres and Mendosa, they are extremely productive; and wine is made of a secondary class, both dry and sweet, red and white. Some is sent to the United States. Peru produces delicious grapes; and wine is manufactured in some places, which, by proper management, might be excellent. That of Pasco is the best, where the Muscatel grape excels that of old Spain.

3401. To make out a mere list of the numerous wines made in the various countries of the world would be almost impossible. In the following table are placed the most remarkable of those which are imported into this country; and a few, perhaps, only known at present by name.

French Wines.

Red Wines.

1st class.
Romanée Conté.
Romanée St. Vivant.
Clos Vaugeot.
Chambertin.
Richebourg
La Tache.
St. George.
Clos de Tart, St. Jean, Le Perriere, Mont Rachet, Muscigny } Burgundies.
Lafitte, La Latour, Chateaux Margaux, Haut Brion } Bordeaux wines.

2d class.
Verzy.
St. Thierry.
Vosne.
Red Hermitage.
Cote Rotie.
Roussillon.
Pomard.

3d class.
Hautvilliers.
Mareuil.
Fleury, Blagny, Santenay, Clarion } Burgundies.
Crozes.
Gervaut.
Chateauneuf.

White Wines.

1st class.
Mont Rachet.
Hermitage.
Riversaltes.
St. Bris.
Pontal.
Sauterne.
Barsac.
Sillery, Ay, Marceuil, Dizy, Hautvilliers, Pierry } Champagne.
La Perriere, Goutte d'Or, Combotte, Genevrière } Burgundies.

2d class.
Menil, Oger, Cramaut } Champagne

3d class
Vaumorillon
Grenouille.
Chablis.
Valmare.
Vandesir.
Pouilly.
Etoile.
Frontignan
Lunel.

Wines of the Rhine and Moselle—Hocks.

Rhine.
Schloss Johannisberger.
Johannisberger.
Reinberger.
Rudesheim.
Laubenheimer.
Kœsterich.
Niersteiner.
Œstricher.
Zoruheimer.
Hockheimer.
Graefenberger.
Oppenheimer.
Vaskenheimer.
Roth.
Koningsbach.
Ungstein.

Moselle.
Braunenberger.
Scharzberger.
Graach.
Zettingen.
Wehlin.
Piesport.
Reinsport.

Wines of Portugal.

Red or Ports.
Pezo de Regna.
Abasas.
Villarinho des Tricres.
Gorvaens.
Hormida.

White Wines.
Carcavellos, or Lisbon.
Bucellas.
Setuval.

Wines of Madeira.

Malmsey.
Madeira.
Sercial.
Tinto.

Wines of Italy and Sicily.

Lachryma Christi.
Reggio.
Ovieto.
Asti.
Aleatico.
Mazara.
Marsala.

SUBSECT. 9.—*On mixing Foreign Wines in the Manufacture, and particularly with Brandy.*

3402. Wines of the first quality, whose principal merit consists in the bouquet, are never mixed with any other, but each variety is preserved as much as possible in its natural pure state, being marked according to the year of the vintage; and the wines of certain favourable years are much more highly esteemed than others. But the second-rate produce of certain vintages in unfavourable seasons, and of particular vineyards in all seasons, require to be mixed with other wines to correct some bad quality or defect. These mixtures are made by the wine-growers or the foreign merchants, and are often done very judiciously by persons who have great skill in thus improving the wines; these are not, therefore, considered as adulterations, because the wines which are added are equally expensive with the others. Thus, to weak wines are often added those of a more generous nature; and certain wines will not keep sufficiently long without being mixed with others. They are also mixed to suit the taste of different markets; thus, wine prepared for Paris is different from that made up for London, and those for Russia or Germany require a peculiar treatment. It is said, however, that wines consumed in France are less mixed than such as are sent to other countries, probably because people there are more accustomed to the taste of pure wines; and it is impossible by any mixing to produce the qualities of the first growths. Respectable wine-growers or dealers never sell mixed for pure unmixed wines, as the former are always inferior in price. No rules can be given for mixing the produce of different vintages or vineyards with each other, as it must depend upon so many variable circumstances; the taste alone, and experience, can indicate the state of the wine, and the quality and quantity of that which it is proper to add, and this can only be done properly by persons much accustomed to this business.

3403. *One of the great evils in many of the foreign wines imported into England is the large addition made to them of brandy*, which all physicians who have written on this subject consider to be injurious to health. It was at one time supposed that alcohol did not exist ready formed in pure wine, but only the elements of alcohol; and it was imagined that these combined and produced the alcohol during the process of the distillation. This opinion was rendered probable by some curious facts. It is found that the chemist can obtain, by distilling Madeira, Port, or Sherry, nearly one fifth their bulk of alcohol; so that a person who drinks a bottle of either of them will swallow nearly a quarter of a pint of pure spirit as strong as brandy; yet every one knows that the latter would produce a more intoxicating effect than a bottle of wine. It was agreed, therefore, that, according to chemical language, alcohol was the *product*, and not the *educt*, of the distillation of wine; that is, that it had been produced, or actually formed, by the process of distillation which had been employed in analyzing the wine, and had not been merely extracted ready formed from the wine in which it existed. This opinion had originated with Rouelle, a French chemist, and had been supported in this country by Dr. Macculloch and others.

It was, therefore, very important to determine what was the fact; for, if this opinion is well founded, it would account for the difference of effect obviously produced by taking a bottle of wine, or a quarter of a pint of brandy; and it would follow that, if no alcohol ready formed really existed in wine, this beverage did not, and could not, produce the same injurious consequences on the stomach as spirits and water. Careful experiments upon wine were, therefore, instituted, a few years back, to determine this interesting question; but, unfortunately for the theory, the result of these was unfavourable to it. Gay Lussac separated the alcohol from wine at a temperature of 66°, which was considered as too low a heat to effect that combination of principles that had been supposed to give rise to the alcohol; and since that time, the same thing has been done even at 56°, and in a vacuum. It has been, therefore, concluded that wine does contain alcohol already formed in it; and this conclusion has been confirmed, and the question nearly set at rest, by experiments made by Professor Brande, who, without any additional temperature, and by other chemical methods which, it is thought, cannot possibly cause the formation of alcohol, has separated this liquid from a great variety of sorts of wine.

Notwithstanding this decision, however, the fact of the difference in the effect on the constitution which we have mentioned, between a quantity of pure brandy or brandy diluted with water, and an equal quantity in wine, remains unaccounted for. There must, therefore, exist some cause that modifies the intoxicating power of alcohol in wine, so as to occasion it to produce less effect than when taken by itself, or with water only. Physiologists are already well acquainted with the extraordinary effects of chemical combination, and even of mixture, in modifying the activity of substances upon the living system; that the alcohol in wine is combined in some though unknown manner, is rendered probable from the fact, that if brandy be added to wine during its fermentation, it is not so easily separable as if it be added when the fermentation is completed, entering into union with some of the principles of the wine. Thus, brandy added to wines after they are brought to England is much more easily perceived by the palate, and is more injurious to the stomach, than when it has been added during the fabrication. Some imagine that the acids contained in wine modify the effect of the alcohol.

In the practice of Oporto, the complete fermentation of the must takes place in the vat; the wine is then introduced into large tuns capable of holding twenty-five pipes each; and at this stage the brandy is added, according to the discretion of the maker. In Madeira, the second or insensible fermentation is carried on in pipes, and the wine is racked from them at the end of three or four months, at which time a portion of the brandy is added; the remainder is reserved to be mixed at the time of exportation. The process followed in making sherry is rather more complicated, and appears to afford some useful hints relative to the disposal of the brandy which fashion has introduced into the composition of this, as of the former wines. The grapes are first slightly dried, and sprinkled with quicklime; they are then wetted with brandy on being introduced into the press, a farther portion being added to the must before the fermentation commences. By this procedure the brandy is better enabled to combine with the wine, so as to form a fluid more perfect than when it is merely, as in the former cases, mixed with the wine after that is completed. The subsequent process consists in repeated racking, at intervals of a month or two, till March, brandy being added at each of these operations.

3404. Still, in whatever way the brandy is added, the result is injurious to the human constitution; and such brandied wines are relished only by those whose palates are accustomed to them. The diseases which destroy spirit drinkers, chiefly liver complaints, are frequent among those who are in the habit of using constantly the strong-brandied wines; and such ill health is to be attributed to the alcohol with which the wine is adulterated rather than to the wine itself, such complaints being rare in those countries where pure unadulterated wine alone is drunk. These observations apply, as we shall afterward show, equally to the addition of brandy to our domestic wines, which are supposed, erroneously, to require this addition, but by which they are rendered extremely unwholesome.

SUBSECT. 10.—*Table of the Quantity of Alcohol in several kinds of Wine and other Liquors analyzed by Brande, Prout, &c.*

	Alcohol in 100 parts by Measure.
Port	from 25·83 to 19·00
Colares port	" 19·75
Madeira	" 24·42 to 19·24
Red Madeira	" 22·30 to 18·40
Cape Madeira	" 22·94 to 18·11
Sherry	" 23·80 to 18·25
Teneriffe	" 19·79
Lachryma Christi	" 19·70
White Constantia	" 19·75
Red Constantia	" 18·92
Calcabella	" 11·20 to 18·10
Vidonia	" 19·25
Roussillon	" 19·00 to 17·26
Shiraz	" 19·80
Bucellas	" 18·49
Lisbon	" 18·94
Malaga	" 18·94 to 17·26
White Hermitage	" 17·43
Claret	" 17·11 to 12·91
Zante	" 17·05
Marsala	" 17·26
Burgundy	" 16·60 to 11·95
Aleatico	" 16·20
Malmsey, Madeira	" 16·40
Syracuse	" 15·28
Lunel	" 15·52
Nice	" 14·63
Hock	" 14·37 to 8·88
Sauterne	" 14·22
Constantia	" 14·50
Tent	" 13·20
Barsac	" 13·86
Vin de Grave	" 13·94 to 12·80

	Alcohol in 100 parts by Measure.
Champagne (still)	from 13·80
Champagne (sparkling)	" 12·80
Champagne (red)	" 12·56 to 11·30
Red Hermitage	" 12·32
Frontignac	" 12·79
Cote Rotie	" 12·32
Rudesheimer	" 10·72
Johannisberger	" 8·71
Œstrichen	" 8·46
Zornheimer	" 8·75
Rhenish wine	" 7·58
Tokay	" 9·88
Raisin wine	" 26·40 to 23·20
Currant wine	" 20·55
Grape wine	" 18·11
Gooseberry wine	" 11·64
Elder wine	" 9·87
Cider	" 9·87
Perry	" 7·26
Mead	" 7·32
Burton ale	" 8·88
Edinburgh ale	" 6·20
Dorchester ale	" 5·56
Brown stout	" 6·80
London porter	" 4·20
London small beer	" 1·28
Brandy	" 53·39
Rum	" 53·68
Gin	" 57·60
Scotch whiskey	" 54·32
Irish whiskey	" 53·90

3405. The following list of average prices of wines, as sold by wine-merchants in London, may serve to give some idea of their comparative cost:

	Per Doz.
Port.	
Port from wood	from 24*s.* to 30*s.*
Port, crusted, two years in bottle	" 36*s.*
Port, four years in bottle	" 42*s.*
Port, eight to ten years in bottle	" 45*s.* to 60*s.*
Sherry.	
Pale and brown	" 24*s.* to 30*s.*
Pale, old	" 36*s.* to 42*s.*
Pale, superior brown	" 48*s.* to 60*s.*
Lisbon.	
Lisbon	" 24*s.* to 36*s.*
Mountain	" 21*s.* to 42*s.*
Sweet Lisbon, and Carcavella	" 36*s.* to 42*s.*
Bucellas	" 36*s.* to 42*s.*
Madeira.	
Malmsey, Madeira	" 54*s.*
East India, direct	" 40*s.* to 60*s.*
West India	" 40*s.*
Vidonia	" 30*s.* to 36*s.*
Rota Tinta	" 48*s.*
Sicilian.	
Marsala	" 21*s.* to 24*s.*
Mazara	" 26*s.*
Cape Wines.	
Cape	from 15*s.* to 18*s.*

	Per Doz.
Cape Madeira	from 18*s.* to 24*s.*
Constantia	" 48*s.* to 60*s.*
Rhenish.	
Hockheim	" 42*s*
Rudesheim	" 64*s.*
Moselle	" 6*s.* to 54*s*
Johannisberg	" 72*s.*
Tafelwein—table hock	" 36*s.*
Champagne.	
White sparkling	" 60*s.* to 66*s.*
Ai Mousseux	" 72*s.* to 78*s.*

SUBSECT. 11.—*Wines of the Ancients.*

3406. We shall not detain our readers long on the subject of the wines of the ancient nations, but a few words will not be misplaced to fill up our sketch of the historical part of this subject; and particularly as this beverage, so much esteemed among the Greeks and Romans, is often alluded to by classic authors. It is proper to state that we are indebted to the elegant work on wines by Dr. Henderson for many of the leading facts on this interesting subject.

3407. *The invention of wine* must date from that period when truth cannot be separated from fable: it was ascribed to Bacchus by the Grecian poets; and, no doubt, when once discovered, the knowledge of so fascinating a liquid soon made its way through the civilized part of the ancient world.

3408. *The effect produced by the fermentation of vegetable matter must have been perceived shortly after the commencement of gardening and agriculture.* When the juice of fruits, the grape, for instance, was kept for some time, this fermentation would appear in a very evident manner; nor was the result less striking; instead of the sweet luscious taste peculiar to the grape, it would be found, after the fermentation was over, to have acquired new flavour and other properties. Its taste had become what we now call *vinous;* and, after drinking it, a delirium of the senses was felt, to which we give the name of *intoxication.* We can very easily conceive that mere accident might have led to this discovery, which appears to have been made at a very ancient period of human history. We learn from Scripture, that Noah "planted a vineyard; and he drank the wine, and was drunken." Whether this was the commencement of fermented liquors it would be useless now to inquire; but there can be no doubt but that the person who was first intoxicated must have been so from entire ignorance of the nature of that state. Happy would it have been for man if he had always remained in that ignorance; or, with this addition to his knowledge, had he been sufficiently impressed with all the dangers that might result from his discovery! But it is with this as with many other things; he too often converts that into evil which, under proper guidance, might prove a benefit.

3409. *The grape, like most of our fruits, appears to have come originally from the milder climates of Asia.* Palestine, at an early time, abounded in vineyards, and the manufacture of wine was known to the Hebrews; the wines of Damascus and of Lebanon were celebrated. But it does not appear that the vine was cultivated, at least to any extent, in ancient Egypt; there corn was produced in abundance, and from it the Egyptians prepared an intoxicating liquor, probably analogous to beer, which is at present made in many parts of Africa. Among the Greeks, wine was a favourite beverage, and its virtues have been highly extolled by their poets. In the time of Homer, the wine of Maronea, in Thrace, was made of great strength; and that of Cyprus, Lesbos, and Chio were long in high estimation, and were exported to Rome. The cultivation of the vine was not introduced into Italy till 600 years after the foundation of Rome; but it became afterward an object of diligent attention among the Romans, and we find ample directions in their writings on agriculture for their management. They frequently trained their vines on lofty trees to the height of thirty or forty feet, from an idea of improving the grapes, although in modern times this practice is condemned. In general, the processes for the manufacture of the wines used by the common people probably did not differ much from some that are employed at present; the fruit was collected, bruised by the feet or subjected to a press, and fermented much in the same manner as it is now.

3410. *But they were likewise in the practice of preparing richer and sometimes more durable kinds of wine,* the nature of which has given rise to much speculation. Some of these wines, and the manner of producing them, are described by Pliny. The juice of the most luscious grapes was expressed, and kept as much as possible from the contact of the external air, by which the fermentation would be very slight, and the full flavour of the fruit preserved; and in some cases the must was put into an amphora well pitched and sunk in a pond or in the sea for a month or more, until it nearly lost all tendency to ferment, and was then in a state between a sirup and wine. They also prepared a rich wine, called *passum,* from the juice of grapes half dried.

3411. *Both Greeks and Romans were in the habit of concentrating their wines by spontaneous evaporation of the must,* or by boiling it till it was reduced to one half, or even one third. By these means the wine was brought to the state of sirup, and required to be diluted with water before it could be drunk. Pliny speaks of wines as thick as honey, which it was necessary to dissolve in warm water and filter. The inspissated wines of the ancients, obtained from rich grapes, may be regarded as corresponding to some modern wines, called *vino cotto,* which are prepared by boiling must; and the practice of boiling the juice of grapes for culinary purposes is common at this time in France and Italy.

3412. *Some of these ancient wines were capable of being preserved for a very long time;* and Horace, in his Odes, boasts of drinking Falernian wine of his own age; indeed, wines of a hundred years old seem not to have been uncommon among the luxurious citizens of ancient Rome. But we are not to suppose that the Falernian and similar wines were of the kind which had been boiled to a sirupy consistence, since this process of evaporation is not necessary, as is well known, to their being preserved, since some of the German wines have been kept for two or three hundred years; but these very old wines have been kept so long more for curiosity than use.

3413. *Independently of these more simple preparations of wine by the juice of the grape alone, the ancients were fond of giving their wines an artificial flavour;* and for this purpose they introduced not only honey, aromatic fruits, leaves, flowers, and seeds, but even pitch, rosin, and turpentine. However extraordinary this taste may appear, we have abundant instances of acquired tastes of a similar kind among ourselves; and traces of this practice may still be observed in modern Greece, where wines are still flavoured with pitch. The origin of this taste may, perhaps, be traced in the necessity they were under of rendering their skins, the earliest receptacles for wine, impervious by means of oils and resinous substances, a practice common at present, and likewise of coating with pitch, instead of glazing, their large earthen vessels in which wine was generally preserved, casks of wood being seldom used. Few of the ancient wines probably contained much alcohol; they were chiefly esteemed for their fine flavour and sweetness;

and, when these qualities were naturally wanting, they supplied the defect by adding aromatic substances. But of all the ingredients employed in preparing these mixed wines, that of sea water is the most singular; and there is no doubt but it was occasionally used, although it would be difficult to reconcile this practice to modern palates.

3414. *Another practice of the ancients for mellowing* those wines which were of a harsher quality was by exposing them to the heat of the sun, or placing them in apartments warmed by flues, called *fumaria.* This does not appear to differ much from the modern method of improving Madeira by keeping it in a hot-house, or in the vicinity of an oven or kitchen fire, to produce early maturity. The Greeks, in particular, surpassed all other nations in their luscious sweet wines, the best of which were the products of the islands in the Ionian and Ægean Seas, where the fineness of the climate brought the grapes to an extraordinary degree of perfection; among others, the Lesbian and Chian wines were much celebrated. But, besides these sweet wines, the ancients were not unacquainted with the manufacture of dry wines, and, in some degree, with the sparkling and frothy kinds.

3415. *All attempts have been, and probably ever will be, fruitless* in endeavouring to discover what was the taste, flavour, or even the colour of the best wines of the ancients, so as to compare them accurately with those of modern date. A principal difficulty in the description of the qualities of various wines arises from the imperfection of language, which is scarcely capable of conveying in a perfect manner, by any selection of words, the flavours peculiar to certain wines. It is true that when qualities are of the ordinary or usual kind, they may be nearly discriminated by certain expressions; thus, port may be described as rough or astringent; Rhine wines as sharp or tart; malmsey, bitter, sweet, &c. But no terms can convey an accurate idea of all the delicate and nice distinctions which the palate readily perceives, and which each person will endeavour to express in such language as appears to him fittest for the purpose, but which will seldom be found to convey any other than ideas extremely vague. It is probable, from the descriptions, that some of the wines of ancient Greece were not unlike those made in that country in the present day. Others are supposed to have resembled the sweet, luscious wines of the south of Europe, as those of Malaga; and Dr. Henderson considers it as highly probable that the Falernian wine had the strongest analogies with our sherry and Madeira.

Sect. III.—Manufacture of British or Domestic Wine.

Subsect. 1.—*Wine from British Grapes.*

3416. *Introduction.—We have already stated the superiority of grapes above every other fruit employed for making wine,* and that, indeed, it is the only fruit from which wine, properly so called, can be produced. The climate of Great Britain is certainly unfavourable to the successful cultivation of the vine, and a general impression prevails that it is too cold for this purpose. Still it would be interesting to ascertain with accuracy how far art can, in this as well as in many other cases, overcome the difficulty which nature has placed before us. Various kinds of what are called *home-made wines* are annually produced in England from grapes, and likewise from other native fruits; and although it is not possible by any management to render the latter equal to grape wine, yet they are extremely capable of improvement by a judicious mode of manufacture.

3417. *Grape wine being the standard of perfection for vinous fluids,* the nearer approach that is made to it in the fabrication of any other wine, the better it must be. It is essential, therefore, that the maker of domestic wines should first understand clearly the principles of preparing that procured from the vine; and with this view we shall lay down the best rules drawn from successful experiments and the theoretical opinions of those scientific men who have devoted much attention to the subject.

History of British Wine.

3418. *The grape not being indigenous to Britain,* wine was probably unknown to its inhabitants previous to the Roman conquest, except it had been brought by the Phœnicians, who are said to have planted the vine in some of the Mediterranean islands. It is supposed that it was only towards the latter term of the Roman power in this island that the vine was properly cultivated here.

3419. We are informed that about A.D. 85 vineyards in Italy had so much increased that agriculture was neglected, in consequence of which Domitian prohibited planting any more; and that it was upon the removal of this edict by Probus, A.D. 280, the cultivation of this plant was extended to Great Britain, as well as the northern parts of Gaul and the banks of the Rhine. However this may be, and whether or not the Roman nobility of Britain were obliged at first to import their wine, it is probable that vines grew in England at the time of its invasion by the Anglo-Saxons; for Bede the historian informs us that there were several vineyards here in his time, A.D. 731.

3420. At the time of the Norman conquest, it is certain that the culture of the vine had made some progress in Britain; for, in Domesday Book, mention is made of vineyards eight-and-thirty times, as well as of orchards and gardens: there was one at Westminster, another at Ware in Hereford, and even Holbourne had its vineyard belonging to the Bishop of Ely. We find a record that there was an enclosure among the lands of Suien in Essex of six arpents, which in good seasons yielded twenty modei (hogsheads) of wine. The Isle of Ely was denominated *L'Isle des Vignes* by the Normans, and the Bishops of Ely, shortly after the conquest, received annually three or four tuns of wine as the tithes of the vines in his diocess. In the archives of the church of Ely there is preserved an account of the produce of a vineyard for two or three years; even the number of bushels of grapes sold is recorded, as also the value of the wine; and an unfavourable year is mentioned in which no wine was made, but only verjuice.

Bede describes the domain of Thorney, in the Isle of Ely, to be an earthly paradise, and observes that "it is so fully cultivated that no portion of the soil is left unoccupied. On the one hand, it may be seen thickly studded with apple-trees; on the other, covered with vines, which either trail along the ground, or are trained on high, and supported on poles."

3421. The essays of Mr. Pegge in the Archæologia, with the subsequent controversies which originated in the opposition of Mr. Daines Barrington, have established beyond doubt the fact that vineyards were attached to the more considerable monasteries of Britain, at least in the southern parts of the kingdom, for the purpose of making wine. These establishments were generally placed in fertile and well-sheltered valleys, where the choicest exposures of the vine might be found; and the monks possessing most of the learning and knowledge of these times, they were, no doubt, familiar with the best modes of culture of this favourite plant, as we find they were of other vegetable productions, many of them being foreigners from Italy and France. Numerous examples are upon record of the vineyards attached to the abbeys about this period: according to Somner, Canterbury Church and St. Augustine's Abbey were possessed of numerous vineyards; and the Bishop of Rochester made wine, a present of which he sent to Edward II. The rolls of the Exchequer contain an account of certain expenses incurred for the royal vineyard at Rockingham; and, if we credit William of Malmsbury, large tracts of country in various parts of England produced excellent wine in the twelfth century, particularly the vale of Gloucester, where a sweet, palatable wine, little inferior to that of France, was made in abundance. Indeed, in this place grapes grow with great luxuriance in the present day, and without doubt could be raised in great plenty by proper care. We are told by Stowe of the yearly account of the wine produced from grapes grown in the little park at Windsor in the time of Richard II., part of which was used in the king's house, and the rest sold.

3422. It is possible that some of these vineyards belonging to wealthy individuals might be kept as much for amusement as profit; but still we have abundance of proof that wine was formerly made in England in considerable quantity. Foreign wine was, however, imported into the country at an early period; and as it could be had of much better quality from abroad, and perhaps often at less expense than when produced in the island, it is not likely that the supply of the latter was ever sufficient for the consumption of the country; and it is probable that the uncertainty of the climate formed a considerable impediment to the culture of the vine, which limited the use of this beverage to the wealthier classes. But notwithstanding this, enough was raised to render the cultivation of the wine an object of study, until the acquisition of French provinces, under Henry III. and Edward III., gave a taste for the wines of that country, and rendered them so cheap as to occasion a neglect of our native wines, which were analogous to those of the Rhine.

3423. *In the year* 1273, 8846 *tuns of foreign wine were brought to England*, paying one penny per tun duty, of which London imported 3799 tuns; Southampton and Portsmouth, 3147; and Sandwich, then a great seaport, 1900. At that period wine was very plentiful in the houses of the nobility and gentry; and so cheap were French wines, that in the reign of Henry VIII. they were sold at eightpence a gallon.

3424. *The chroniclers of the time complain that this abundance of foreign wines caused the first neglect of the English vineyards*, which was completed by the dissolution of the monasteries. It was not only in England, but in other countries, as in France, that the cultivation of the vine was more attended to by the clergy, who were at one time almost the sole depositaries of learning, and had much leisure and opportunity for observation and study. On the lands of the rich monasteries were to be found the choicest growths of the vine, the quality rather than the quantity of the vintage being the object in request. No pains were spared in the improvement of the soil, and in the dressing and management of the vine, and the fermentation of the juice. When ecclesiastical domains in France passed into the hands of laymen, the same assiduity and skill were not shown in the cultivation of the vine, and in the hands of wine-manufacturers quantity was preferred to the quality of the produce. It is a fact that at this day many of the best vineyards in France are on the sites of lands that once belonged to the monasteries.

But, in order to cover the harshness which belonged to the greater part of the wines of that period, it was usual to mix with them various sweets and spices, and a sort of liquid called *piments* were compounded, not very unlike some of the liqueurs of the present day, served at feasts and entertainments, as exquisite luxuries. Of this kind was the *Ypocrase*, prepared, when "*for lords*, with wine, gynger, synamon, graynes, sugour, and turesoll; and when *for comyn pepull*, of wine, gynger, canell, longe pepper, and clarified honey." *Clarry* was a similar mixture of wine, honey, and some spices; and the *Bishop* of our days, made of wine, oranges, and sugar, is probably a remnant of these ancient beverages. The taste for sweet wines was considerable, and we find that the malmseys of Candia and the rich wines of Greece and Spain were much in request.

3425. *In the time of Queen Elizabeth no less than fifty-six kinds of foreign wines were imported*, French, Italian, Spanish, Canary, Cyprus, Malmsey, &c.; and this profusion displayed on the table was not confined to England, but was seen in Scotland also.

Most probably the dissolution of political bonds between England and the French provinces which she lost might have diminished the facility of importation, and the consumption of Bordeaux wine; we find that afterward the strong wines of Spain came more into use, and early in the sixteenth century they had almost superseded the milder growths of France. In the reign of Elizabeth and James I. "your *sack* was the only drink;" and there has been much diversity of opinion as to the class of wines those called sacks belonged. It appears that the name was originally applied to certain white wines of Spain, and was a corruption of *seck*, or *sec*, signifying a dry wine. The original sack was probably not unlike sherry; and this name came afterward to include similar wines, as those of Malaga and the Canaries, with malmseys and other sweet wines, which probably had at that time the same character by which they are at present distinguished. But although these wines were held in the greatest estimation, the light wines of France and the Rhine were still much in use, until all commercial intercourse with France ceased during the long wars with Louis XIV., which gave rise to the introduction of the wines of Portugal, the history of which we have already given when describing the wines of that country. Nevertheless, the cultivation of the vine was continued in England during the reign of Queen Elizabeth; and Barnaby has pointed out the vineyards of Lord Cobham and Willienus of Thames as eminently productive.

3426. *About the end of the fifteenth century agriculture was more attended to*, and malt became more plentiful; the hop was likewise introduced into the country, which gave rise to a great improvement in the ale, and rendered it a beverage accessible to the people generally. From this, and the high duties laid on wine, the use of the latter gradually declined, and malt liquors were more used.

3427. *We have several well-authenticated accounts of wine having been made in England at a period not very far back*. In the "Museum Rusticum" it is stated that at Arundel Castle in Sussex, the Duke of Norfolk had a vineyard which annually yielded considerable quantities of wine; of which there were in his grace's cellar, in 1763, above sixty pipes of wine resembling Burgundy. Bradley informs us that Warner, a gentleman of Rotherhithe, made good wine from his own vineyards. Switzer mentions several instances, and, among others, that of Rocque, of Waltham Green, who made wine for thirty years from a vineyard he had planted in a common field garden. Hanbury and Hales confirm these accounts, and cite others. It is said that Dr. Ralph Bathurst, President of Trinity College, Oxford, made as good claret in 1605 "as could be wished for."

But the best account we have of an English vineyard of modern times is that by Sir E. Barry, the author of a work on wines, in which he describes a very productive one formed by the Hon. Charles Hamilton, at Painshill in Surry, about sixty years ago, from which excellent wine was made. We shall give the whole account as an authentic document when we treat of the practice of making English grape wine. Besides those examples on a great scale, abundant instances occur at present where individuals have made for their families, and from their own grapes, wine equal to the generality of imported table wines, and at less than one third of the expense.

3428. *The cultivation of the vine in Britain, though at present carried to a high degree of perfection in hot-houses for table fruit by the professed gardener*, has been much less attended to for the purpose of making wine than might be expected from what we have stated of the history of British wine. Mr. Hoare, to whom we are indebted for an excellent work on the "Cultivation of the Grape-vine," and to which we refer the reader who wishes to attempt it, observes that "vines are now cultivated in this country only under glass, upon the roofs of buildings, and against walls. The expense of growing the grapes under glass is such as obviously to place that method out of the reach of the mass of the people; and vineyard culture, now that it has fallen into disuse, is, perhaps, considered so much in the light of a commercial speculation, that those who possess the means of practising it are deterred from employing them, from an apprehension that the risk and uncertainty attending it would prove more than sufficient to counterbalance its advantages. But the cultivation of vines on open walls being free from these and all other objections, presents an advantageous method of producing grapes, which may be embraced by every person who has at his command a sufficient number of square feet of the surface of a wall."

3429. *It has been supposed that the established fact of numerous vineyards having formerly existed in England demonstrates that our climate has deteriorated;* but this opinion is wholly without foundation: on the contrary, there is great reason for believing that the climate of Europe has for several centuries past been rather in a state of amelioration, from the clearing of woods, draining of marshes, and agricultural improvements. It must be admitted, however, that, from the uncertainty of our climate, such crops would be liable to occasional failures; and, indeed, by the records of Ely it appears that this was formerly the case. With what advantage the manufacture of domestic wine from grapes could be carried on to a considerable extent in this kingdom is a subject that does not belong to our objects to inquire into; and, indeed, no accurate judgment could be formed without some direct experiments; but that this is perfectly practicable on a small scale for domestic use, and with manifest advantage with a view to economy, there is abundance of proof. Enough is already known to demonstrate the complete practicability of producing wine for the table equal to ordinary Champagne, and some of the Moselle and Rhenish wines of the second and third classes, at less than a half, or perhaps one third of the price now paid for them, with the advantage of being entirely free from adulteration; whereas a great part of the cheap wines called foreign are compositions of the vilest description.

3430. *But the practice of making wine from grapes in England is far from being extinct.* The cottagers in Sussex are in the habit of making wine, almost annually, from the produce of vines trained on the walls of their houses. Many individuals through various parts of the southern counties, and even as far north as Derbyshire, practice the same with success.

3431. *The sorts of grapes best adapted for the culture on open walls* are, according to Mr. Hoare, the black Hamburgh, the black Prince, the black Muscadine, Miller's Burgundy, the Esperione, the Claret grape, the black Frontignan, the grizzly Frontignan, the white Frontignan, the white Muscadine, the Malmsey Muscadine, and the white sweet water. It would not be prudent to try any foreign kinds that have not been acclimated.

3432. *The vine is easily cultivated;* and no fruit-tree grown in this country can be depended upon with more certainty for a full crop, or that will yield a more ample return, than a vine judiciously trained on an open wall; but Mr. Hoare observes that an erroneous idea prevails that a single vine requires for its training a large portion of walling; whereas this opinion has arisen from the general defective method of pruning and managing that plant, whereby the wood is suffered, and, indeed, encouraged, to extend itself beyond the capability of its fruit-bearing powers. The pruning-knife ought to be more used, whereas vines are usually allowed to load themselves with more fruit than they can mature; and when that is the case their strength becomes exhausted, and the fruit is of little value.

One of the principal causes of failure in this country is the neglect of a proper soil: that generally employed has too great depth of mould, in which the roots of the vine are suffered to run, enticing them to raise too much moisture, by which the vegetation is carried on too late in the autumn, so as to delay the ripening process until the sun has lost too much of its power. The soil should be loamy, and not above eighteen inches deep. The subsoil should be of dry materials, containing stones, brickbats, lumps of old mortar, broken pottery, oyster shells, and similar things. Soils that retain wet are injurious. All animal matters may serve for manure, but these are best formed into composts by mixing them with road sweepings, sand, gravel, and broken bones. Though the vines of Champagne grow upon chalky soils, yet these are not so good as those just mentioned for wines that are to keep long.

Walls are best of brick: dark flint walls retain more heat, but are more uneven. The best aspects are those that are southerly; when the aspect partakes of the north, it is unfit. Shelter is essential as well as aspect, wind being very pernicious.

3433. *In planting a vineyard in England,* care should be taken to select the kind of soil most suitable to the vine, as well as such an exposure as consists of southern slopes; and much would depend upon obtaining the proper varieties of vines. The sorts planted at Painshill, where so successful an experiment was made, as well as those most commonly used on the Continent, are the Burgundy, or large black cluster, and the miller's grape, or small black cluster; but the grapes which produce the sweet wines, as the Constantia, malmsey, and Madeira, are varieties of the Chasselas or Muscadine, which is one of the oldest and most common of our grapes. Professor Martyn recommends that in an English vineyard the vines should be trained very near the ground, he having found that by this method of training the grapes were much increased in size, and also ripened earlier. This method is successfully pursued in the north of France. But in this country it is, perhaps, in peculiarly favourable situations only that vineyards will succeed.

Practical Directions for making Wine from British Grapes.

3434. *We owe to the late Dr. Macculloch the first and almost the only attempt to rescue this branch of domestic economy* from the degraded state into which it had fallen. From his chemical and other knowledge, he was eminently qualified to do it justice, and in his luminous essay he has pointed out the scientific principles upon which the whole depends, presenting the philosophy of the subject. He has distinctly expressed his opinion that "wines not to be distinguished from some of those of foreign growth can, in this country, be made from grapes, and at a moderate expense; and that the success of this process is little, if at all, affected by the uncertainty which attends the ripening the grape in our climate." He adds that "it is not too much to say that the use of this fruit is calculated to supersede that of all others for wine, and that its produce is almost the only species of domestic wine which is worthy of serious attention."

3435. It is necessary to observe that, in thus speaking of the possibility of imitating successfully wines of foreign growth, Dr. Macculloch alludes only to the light white wines of France and Germany, for he admits that it would be vain to attempt the manufacture of such as the rich, highly-flavoured Burgundy, or strong heavy wines like Port, Sherry, Madeira, &c.

3436. *We have stated that the mode of proceeding in making wine must depend partly upon the class of wine to be produced;* whether it is to be brisk, dry, or sweet, and no directions can be given of any use that do not take this into consideration, as upon this must depend the proportions of those principles which are to form the wine, saccharine matter, ferment, tartar, and water; and in these must be taken into account, likewise, the condition of the grapes, whether immature, or ripe and sweet.

3437. It may be convenient to the reader, who is supposed to have perused the previous articles on fermentation, and the sketch of the general theory of wine-making, to remind him that to produce a sweet wine it is necessary that there should be more saccharine matter in the must than the ferment can act upon and decompose; consequently, some of it remains in solution in the wine, being the cause of its sweetness. In dry wines the sugar and ferment have been so exactly balanced that both have been entirely decomposed by acting on each other during the fermentation, which has been carried on to its utmost limit. In brisk wines the fermentation has been interrupted a little before it was completed by putting the wine into bottles, in which a slow fermentation goes on, producing carbonic acid gas ready to escape with violence on uncorking the bottles. It is, therefore, in the power of the operator to produce what class he thinks proper by managing the process accordingly.

3438. *It is the usual defect of grapes grown in our climate to be deficient in sugar, and to abound in the fermenting principle.* This is sometimes the case even in the wine countries, and there experience has taught to correct this defect when it occurs, by the addition of sugar, of honey, or of sweet must evaporated by boiling until it has become a thick saccharine fluid. With us sugar is the substance employed for this purpose. It is obvious that the strength of the wine must depend upon the quantity of sugar in the must, or, rather, the quantity decomposed in consequence of fermentation. But there is a limit to the addition of sugar: if too much is added, the ferment will not be sufficient to convert it into alcohol, and the overplus will remain in the wine, merely rendering it sweet; the water will, likewise, then be in too small proportion, and the must will be too thick to ferment readily. But the whole of the sugar is seldom decomposed during the first stages of fermentation; a portion is frequently attached to the wine, even those considered dry, long after they are put into casks, and even after they are bottled. It is only by the slow fermentation in casks and bottles, a process that often requires years for its completion, that the sugar is entirely changed into alcohol and combined with the other ingredients of the wine.

3439. *To make a brisk wine resembling Champagne,* the grapes may be used in any stage of maturity in which they are most conveniently obtained. Those of different degrees of maturation may even be mixed together, nor is it requisite to attend to the selection of any particular variety. It is rarely, indeed, that we are allowed any choice in this matter. It is a great advantage, which affords greater facility in making this kind of wine, that it is not essential that the whole, or, indeed, any of the fruit should be ripe.

Unripe grapes will, in general, be found equal, if not superior, to those which are ripe; for, though the former are deficient in saccharine matter, the latter, with us, has seldom a great deal. Though our ordinary grapes, with the exception of those raised in hot-houses, are deficient in sweetness, this defect can be supplied by the addition of sugar to the must: the fermenting principle and the tartar are therefore of more value, which diminish with the maturity of the fruit. The price of ripe fruit, also, is higher. The skins and stalks of the grapes may be subjected to the fermentation, or not: in making Champagne they are better separated; keeping them in will give an austerity which in some other wines is desirable: the seeds should not be bruised. In general, it will be preferable to wait till the grapes exhibit the first tendency to ripen, or till the advance of the cold season shows that no farther ripening can be expected: but a small proportion of crude grapes is useful: and where the vine is largely cultivated, fruit for this purpose may be obtained from the thinning usually practised.

3440. The method of bruising the grapes to extract the juice is, in many parts of the Continent, extremely imperfect: treading with the feet effects it very unequally. A press of some kind is preferable, and it should be one of considerable power, to extract perfectly the tartrate, which lies mostly in the skin. In the wine countries the very best wine is sometimes made from juice obtained with scarcely any pressure: this, in Italy, is called *vino virgine*. In England the quantity employed and the state of the fruit will render this impracticable.

3441. It is essential to the success of the fermentation that the water should be added in the right proportion, in order that the fluidity of the must may be sufficient When Champagne is intended, there should be equal quantities of water and grape-juice.

3442. The proportion of sugar added to the must will, in some degree, determine the strength of the wine. Two pounds of sugar to a gallon of the mixture will yield a light wine of no great durability, resembling the lighter sorts of Champagne; and three pounds of sugar will give a strength equal to the best sorts. Sugar from the cane is not exactly of the same species as that from the grape, as we have shown in another place; but this difference is not appreciable in the spirit produced from each of them Yeast is not necessary; but it is too common to add it. The phenomena of fermentation having been amply described in previous parts of this work, we need not repeat what has been said.

3443. For brisk wine the must should be put into the cask at once, as the fermentation there will be sufficient. The best temperature is about 62°. The time employed in the fermentation must depend upon a variety of circumstances, as the weather, the composition of the must, and the sort of wine to be made; of course, it must be regulated by a knowledge of general principles and experience.

3444. The practice followed in France is described as follows: "The fermentation will sometimes not begin so soon as might be expected, but the operator must not be impatient; it will not finally be less effectual because it has been more tedious; and increasing the temperature a little will generally produce a commencement, and continue it. If the fermentation should be too languid during its progress, it may be increased by agitating the cask, or by omitting to replenish it to the bung, so that the scum or head may be compelled to remain in the liquor. The first fermentation in the casks is violent, and the discharge of the yeast is encouraged for ten or twelve days by keeping them full to the bung-hole; it then becomes more moderate when the bung is put down, and a gimlet hole fitted with a spile is made by the side of it. When the cask is thus closed, the vent-hole is opened every day or two, according to the state of the fermentation, for a space of eight or ten days, to allow the carbonic acid to escape. When this state is passed, fresh wine reserved for the purpose is poured in at the vent-hole about once a week for the first three or four weeks, according to its waste, so as to fill the cask; this operation is then performed at longer intervals of a month or more, till the end of December, when the wine usually becomes clear. It is afterward decanted from the lees into a fresh cask, where it is fined with isinglass, in the proportion of half an ounce to a pipe; and this process of decanting is carefully executed in dry, clear, frosty weather. A new fermentation is now excited, by which the wine loses a portion of its sweetness, and becomes farther ameliorated. If it should prove too sweet, this first operation of decanting is not performed until the fermentation in the first cask has been rendered more vigorous, which is done by stirring up the lees or rolling the cask; and by this the sweetness is overcome, and the wine strengthened and improved. To ensure the fineness of this wine, which is one of its essential properties, and to render it at the same time durable, it is, at the end of six weeks, decanted a second time into a fresh cask, and once more fined with half the quantity of isinglass; it is then completed, and is put into bottles in March, clear, dry weather being also chosen for this purpose. In the bottles the farther fermentation will go on in a very slow and almost insensible manner, because the carbonic acid which is produced will be confined, and absorbed, and condensed by the wine, as it would be in water by means of pressure, but will escape on decanting, with the appearance and noise which brisk wines exhibit, upon the same principle as when it escapes from soda water. This gas, being itself an acid, communicates an agreeable and peculiar acidulous taste, which constitutes one of the most valuable qualities which these wines possess. It can scarcely be necessary to observe that this abundance of gas, though it adds to the briskness, is no proof of the strength of the wine, as this depends upon another principle, the alcohol. The production, therefore, of brisk wines must be effected by so contriving the process that a great quantity of carbonic acid gas shall be enclosed with the wine in the bottle. For this purpose two fermentations are necessary; the first, by which the juice of the fruit was converted into a vinous liquor, and during which the carbonic acid that was generated escaped; and the second, much slower, which takes place in the bottle itself, and where the gas, in consequence, is retained, and constitutes the briskness of the wine. Notwithstanding all the above-mentioned care, a fresh deposite is sometimes formed in the bottles, from a renewal of the fermenting process which goes on in them. To remove this, and to render the wines perfect, those of the best quality in Champagne are sometimes decanted clear into fresh bottles in about fifteen or eighteen months, when the wine is complete. A certain loss, amounting to about ten, though sometimes to twenty per cent. on an average, is sustained by their bursting previous to this last stage. The brisk ones will be drinkable as soon as they have been six months bottled, or even less; but if of good body, they are better in the following, or even in the third year. After this, or should they from any cause lose their briskness, they generally become dry wines, resembling some of those of France, or of the Rhine and Moselle, while in this case they keep indefinitely, and proceed in improving."

It is easy to perceive, from this description of the mode of manufacturing brisk wines in Champagne, that our grapes, though the produce of a country not sufficiently warm to have this fruit of the first quality, may yet be quite sufficient for the purpose of making brisk wine, or even dry wine of good quality, if great strength be not required.

Those wines only which are capable of continuing in a state of slow fermentation for a long time, can be brisk. The richest juices, therefore, which contain the greatest quantity of saccharine matter, are not calculated to form brisk wines; on the contrary, these are prepared *best* from fruit that has not quite ripened. For the fabrication of such wines, much of the natural fermenting principle is necessary, which is most abundant in unripe fruits, a fact which must be well known to those who attempt to imitate Champagne wines by gooseberries, since the object, however easily attained by using the immature fruit, is nearly unattainable with the ripe.

3445. *A few additional directions respecting the fermentation* of brisk wines may be useful. If the temper ature be less than 62° the fermentation will be too feeble, and if much higher it will be too rapid, and there will be great danger of its running into the acetous stage. If the quantity of must be small, a greater degree of heat is necessary than when it is large, because the heat excited by this process increases with the quantity of the fluid. Strong musts will also bear a higher temperature than weak ones, as the alcohol produced has the power of checking fermentation, and also of preventing the wine from becoming acid. It is not uncommon, in the manufacture of domestic wines, that, from not attending accurately to the temperature, it is suffered to rise too high, and, consequently, some acetic acid is generated, which cannot afterward be got rid of. When the fermentation is slow in beginning, a little warm must is sometimes introduced to the bottom of the vat by means of a long funnel. In order to check the fermentation when in danger of proceeding too far, from the fermenting principle being in too great quantity, several modes may be adopted. Sugar may be added to the must, that the ferment may act upon this in producing more alcohol, and thus increase the strength of the wine, instead of causing the acetous fermentation to come on, or the fermentation may be checked by racking. Fermentation is always more rapid in large than in small vessels, which may explain the difference that may be perceived in making ten or two gallons of wine. But the flavour is best preserved when the quantity is small and the fermentation slow.

3446. *The intoxicating property of brisk wines*, like all others, depends chiefly upon the alcohol; but the reason why they produce this effect so rapidly is supposed to be that the alcohol and carbonic acid are held in some peculiar state of combination when they are applied to the nervous system.

3447. *The colour of wines from grapes*, though an important circumstance in foreign wines, is one that does not here demand our attention, as red wines are seldom attempted with us. It has been already stated, that the juice of all grapes alone produces only colourless or white wine, the colour residing in the skin of the grape. When a red colour is required, the skins of red grapes are fermented together with the juice, when the newly-formed alcohol dissolves the colouring matter. With respect to artificial colouring, it is probably much better omitted. The claret grape may, however, be employed for this purpose.

3448. *We have now shown that a compound or artificial must* can be fabricated from due admixtures of sugar with the natural ferment of the grape and the saline part of the fruit, which is capable of undergoing a regular fermentation, and of forming good and perfect wine. Experiments have been made long ago in France with green grapes and sugar, and with complete success: these experiments have been repeated by Dr. Macculloch, and thus have been produced wines resembling Champagne, Grave, Rhenish, Moselle, St. Peray, and white Hermitage, and of qualities so perfect that the best judges and wine-tasters have not been able to distinguish them from foreign wines. When sugar is employed, it is probable that the sugar now made from starch or potatoes will be the best, being the same as that of the grape, which, as we formerly stated, is different from the common or cane sugar.

It is evident that wines made on this principle, that is, from green grapes, will be more expensive than when made from ripe grapes, as a sufficient quantity of sugar must be used to compensate for the deficiency of the natural saccharine matter of the grape. But even then they need be little more costly than currant or gooseberry wines, while, at the same time, their superiority is beyond all competition. The hardiest grapes will produce a wine of the strength of white Hermitage with a proportion of three pounds or less of sugar to the gallon; nor are these wines void of flavour, as might, perhaps, be supposed. Dr. Macculloch states that all the wines made under his direction were characterized by flavours as genuine and decided as those of the foreign wines to which they approximated.

3449. *Dr. Macculloch's receipt for making wine of mature grapes:*

"It is so seldom that a sufficient quantity of these can be procured, that it is almost superfluous to mention this variety of domestic wine; and the reader already knows that the grapes ripened in this country make very indifferent wine, and, indeed, it happens, even in more favoured climates, that the grapes of gardens are noted for producing bad wine. If wine is to be made from ripe grapes, no water is to be used; but as the juice of our fruit is, in general, deficient in sweetness, it is necessary to add a quantity of sugar, varying from one to perhaps one and a half pound for each gallon of *must*. The addition of some tartar to the must is also useful in this case, our ripe grapes being deficient in this principle."

"The general, though not the sole cause, of failure in those wines which are made in this country from ripe grapes is the deficiency of saccharine matter; and even those, as well as the wines from unripe grapes, would be much improved by an addition of sugar to the must. It is owing to this deficiency chiefly that these wines are perishable, and easily pass into vinegar, the natural must containing too much water to produce a durable wine. No positive rules, however, as we have said, can be given for the quantities of sugar to be added, as this must depend upon the degree of sweetness in the grapes."

3450. "If the wine is intended to be dry, like hock, more grapes must be used, with about the same quantity of sugar, or less water, or perhaps this will be best omitted. The fermentation must be allowed to continue long enough to convert all the sugar into alcohol, which will be known by the disappearance of the sweetness. Should it happen that the ferment is rather in too small a quantity to decompose all the sugar readily, it is proper to make the most use of what there is. Instead, therefore, of removing the yeast which rises to the surface, it should be beat down, and mixed again through the fermenting must; and when the liquor is transferred to the casks to undergo the slow fermentation, it should not be made to fill the casks quite, but space should be left for the yeast to collect, and this should be frequently mixed up with the liquor by shaking or rolling. As soon as all the sweetness is gone, the fermentation must be checked, and the wine must be racked into other casks, otherwise it would pass into the acetous stage. The fermentation, if unchecked, would continue, under favourable circumstances, as long as any sugar or ferment remains undecomposed; if these have been in such proportion as exactly to neutralize each other, the fermentation will be perfect, and will terminate naturally; the wine being dry, the ferment, now rendered insoluble and inactive, appearing under the form of yeast and lees. But this nice accuracy is seldom attainable; if the ferment be considerably in excess, the fermentation will proceed from the vinous to the acetous stage, and the whole will become vinegar. It is necessary that there shall be so much saccharine matter that a small portion of it shall still continue unchanged; and this will be the case, though it may not be perceived, because the palate is unable to detect the last portion of sugar, marked as it is by the predominant taste of the wine. This small excess of sugar is necessary to exhaust the ferment, and to prevent the acetous stage. The addition of sugar to wine will, in the same manner, prevent acidity, when it is suspected that this may happen, by exhausting the ferment; but, should acidity have commenced, sugar will only aggravate the evil, by adding material for the acid fermentation to work upon."

"All the dry and sweet wines require to be kept in bottle for four or five years, if it be desired to have them in perfection. The impatience of the makers of domestic wines to enjoy the produce of their art is, indeed, one of the causes of failure. They are generally drunk within a year or two, and long before they are completed, since even the best wines of foreign countries often require many years to bring them to perfection. It is very common for the made wines to possess a bad flavour when first made, not unlike that which has hitherto infested most of the wines of the Cape. Time dissipates this, even in the bottles."

3451. With regard to the durability of these wines, Dr. Macculloch farther observes that he has kept some of them for twenty years, and during all that time with evident improvement. They seem to be as little liable to destruction as wines of the best manufacture; and this, it is to be observed, without the addition of brandy.

3452. If the wine is intended to be sweet like malmsey, the grapes should be ripe, and contain much saccharine matter, or a large proportion of sugar must be used; also the fermentation should not be carried on so far as to change all the sugar; but it must be checked in the first instance, as soon as it is thought to be sufficient for this kind of wine, leaving still a good deal of sugar unaltered; this is done by removing all the yeast and scum as soon as it is formed; sometimes, if it is thought that there is still too much ferment in the liquor for the quantity of sugar, it may be taken out by adding some solution of isinglass, which will precipitate the ferment; or more sugar may be added for the ferment to act upon, and thus increase the strength of the wine. In the wine countries, where much sweet wine is made, this effect is produced in various other ways; sometimes by racking and sulphuring, processes which will be afterward described, by a partial drying of the grapes, or by the addition of boiled must, sugar, or honey.

3453. *The account by Mr. Hamilton of the manner in which the wine was made formerly from the vineyard at Painshill* is so interesting a document, that we shall give it in his own words:

"The vineyard at Painshill is situated on the south side of a gentle hill, the soil a gravelly sand. It is planted entirely with the two sorts of Burgundy grapes: the Auvergnat, which is the most delicate, but the tenderest, and the miller grape, commonly called the black cluster, which is more hardy. The first year I attempted to make the red wine in the usual way, by treading the grapes, then letting them ferment in a vat till all the husks and impurities formed a thick crust at the top; the boiling ceased, and the clear wine was drawn off from the bottom. This essay did not answer; the wine was so very harsh and austere that I despaired of ever making red wine fit to drink; but through that harshness I perceived a flavour something like that of some small French white wines, which made me hope I should succeed better with white wine. That experiment succeeded far beyond my most sanguine expectations; for the very first year I made white wine it nearly resembled the flavour of Champagne; and in two or three years more, as the vines grew stronger, to my great amazement, my wine had a finer flavour than the best Champagne I ever tasted; the first running was as clear as spirits, the second running was *œil de perdrix*, and both of them sparkled and creamed in the glass like Champagne. It would be endless to mention how many good wine-merchants were deceived by my wine, and thought it superior to any Champagne they ever drunk; even the Duke de Mirepoix preferred it to any other wine; but, such is the prejudice of most people against anything of English growth, I generally found it most prudent not to declare where it grew till after they had passed their verdict upon it. The surest proof I can give of its excellence is, that I have sold it to wine-merchants for fifty guineas per hogshead; and one wine-merchant, to whom I sold five hundred pounds' worth at one time, assured me he sold some of the best of it for 7*s*. 6*d*. to 10*s*. 6*d*. a bottle.

"After many years' experience, the best method I found of making and managing it was this: I let the grapes hang till they had all the maturity the season would give them; then they were carefully cut off with scissors, and brought home to the wine-barn in small quantities, to prevent their heating or pressing one another; then they were all picked off the stalks, and all the mouldy or green ones were discarded before they were put upon the press, where they were all pressed in a few hours after they were gathered; much would run from them before the press squeezed them, from their own weight upon one another. This running was as clear as water and sweet as sirup, and all this of the first pressing and part of the second continued white; the other pressings grew reddish, and were not mixed with the best. As fast as the wine ran from the press into a large receiver it was put into the hogsheads and closely bunged up. In a few hours one could hear the fermentation begin, which would soon burst the casks if not guarded against by hooping them strongly with iron, and securing them in strong wooden frames, and the heads with wedges; in the height of the fermentation I have frequently seen the wine oozing through the pores of the staves. These hogsheads were left all the depth of winter in the cool barn to reap the benefit of the frosts. When the fermentation was over, which was easily discovered by the cessation of noise and oozing, but, to be more certain, by pegging the cask, when it would be quite clear; then it was racked off into clean hogsheads, and carried to the vaults before any warmth of weather could raise a second fermentation. In March the hogsheads were examined; if any were not very fine, they were fined down with common fish glue in the usual manner; those that were fine of themselves were not fined down, and all were bottled about the end of March, and in about six weeks more would be in perfect order for drinking, and would be in their prime above one year; but the second year the flavour and sweetness would abate, and would gradually decline, till at last it lost all flavour and sweetness; and some that I kept sixteen years became so like old hock that it might pass for such to one who was not a perfect connoisseur. The only art I ever used to it was putting three pounds of white sugar candy to some of the hogsheads when the wine was first tunned from the press, in order to conform to a rage that prevailed to drink none but very sweet Champagne. I am convinced much good wine might be made in many parts of the south of England. Many parts are south of Painshill, many soils may be yet fitter for it, and many situations must be so; for mine was much exposed to the southwest wind (the worst of all for vines), and the declivity was rather too steep; yet, with those disadvantages, it succeeded many years. Indeed, the uncertainty of our climate is against it, and many fine crops have been spoiled by May frosts and wet summers; but one year balances many disappointments."

3454. This example is of great importance; for the grapes were grown in a situation of which, as to soil and exposure, many parallel instances are to be found almost everywhere throughout the country, and with land of no value whatever for the ordinary purposes of agriculture. It is said that some of the vines may yet be seen on the spot, which is now covered with a plantation of Scotch firs.

3455. Not only can wine be made from the vine in countries where, from the climate, its fruits will not ripen, but chemical examination has proved that the *young shoots*, the *tendrils*, and even the *leaves*, contain certain principles exactly similar to the immature fruit, and they have been employed in the same manner for making the same kind of wine. These had been tried with success in France many years ago; but, as the discovery was little important in that country, where grapes were fruitful, it was neglected. We are indebted to Dr. Macculloch for drawing attention again to the subject; and he states that he has made with these materials wines resembling Champagne and St. Peray, and some quite as good as the ordinary Cape wines, resembling them even in flavour, so as to be undistinguishable. Chaptal informs us that it is sometimes the practice in France to suffer the stalks of the grapes to remain in the fermenting vat. The roughness and austere taste which the stems possess appear, he observes, to be an advantage to some wines, especially to those made in the more northern districts, where the slight astringency imparted by the stems corrects their insipidity, and appears to have the property of making them keep better.

As Dr. Macculloch speaks with the utmost confidence respecting the success of his experiments, we shall quote his receipt.

3456. *Dr. Macculloch's receipt for making wine from the leaves and stalks of the vine.*

"The young leaves may be taken at any period from vines which have been cultivated for this purpose, and from which no fruit is expected. In other cases they may be obtained from the summer pruning. The tendrils and green shoots are equally useful. The claret vine may be cultivated for this purpose, in which case the wine will have a red colour. The leaves are best when young, and should not have attained more than half their growth; they should be plucked with their stems. In the neighbourhood of London they require to be carefully washed to remove the taste of soot, which so often adheres to them; sometimes that is insufficient. From sixty to eighty pounds of such leaves being introduced into a tub of sufficient capacity, seven or eight gallons of boiling water are to be poured on them, in which they run to infuse for twenty-four hours. The liquor being poured off, the leaves must be pressed in a press of considerable power; and being subsequently washed with an additional gallon of water, they are again submitted to the action of the press. The sugar, varying from twenty-five to thirty pounds, is then to be added to the mixed liquors, and the quantity being made up to ten gallons and a half, the process which will be shown in making gooseberry wine is to be followed. Although the water is here directed to be boiling hot, it must be remembered that it is immediately cooled down to that temperature which is most efficacious in extracting the several soluble ingredients of the fruit."

3457. The following additional observations on this curious subject are extracted from the same author: "The difference between young and old leaves is very great; the former contain ten or twenty times the quantity of bitter that the latter do. The old leaves are unfit for the ferment. June is the proper time to pluck them; at this season it is usual to remove leaves from the fruit-bearing vines, so that they may be easily procured; but if vines should be grown for this sole purpose, as they may be in any waste place or hedge-row, being allowed to run wild and unpruned, it will be always easy to procure a sufficient quantity, and in the best condition. In their very best state at least six pounds are required for two of sugar, and it is perhaps preferable to adopt eight and a half; though no rule can be absolute, such is the variation in the extractive produce of the leaves. In the progress of the fermentation, should the wine promise to be too sweet, from defect of ferment, it is quite easy to add a fresh infusion, so as to correct this defect by a renewal of the fermentation. Of the leaves it must be observed, as they scarcely yield anything to the press, they require to be infused in the water for some time before they are subjected to fermentation, and they seem to yield their soluble parts most readily to hot water, without any material alteration in the result—a matter of no surprise, because, though the water be applied at the boiling heat, its temperature is immediately lowered. Tartar appears sometimes to be a useful addition to the leaves of the claret vine; and it may be added in the proportion of half a pound or one pound to ten gallons of the must. One advantage results from the use of vine leaves, the facility with which they are reproduced during the growth of the vine. By this the produce of a small vineyard in leaves alone will be abundant; and even that of a single vine suffered to run wild, branches and leaves will be as great as is required for the use of most families. It must always be remembered that in these cases the price of the sugar is the price of the wine. The expense of utensils and labour is comparatively trifling; and, when the manufacture is upon a small scale, scarcely worthy of regard."

3458. *The expense of making grape wine* must vary with so many circumstances, that it would be impossible to fix any price as a standard, but, from the following statement in the "Gardener's Magazine," it would appear to be very little, at least when of moderate quality.

Materials: Water, 4½ gallons, beer measure; grapes, 5 gallons, beer measure, crushed and soaked in the water seven days; sugar, 17½ lbs., at 10¾*d*. The sugar came to 15*s*. 8½*d*., and the grapes, perhaps, to 5*s*. The cask in which it was made held exactly 6¾ gallons, beer measure, and produced thirty-four bottles of wine clear. A bottle of the above wine, kept ten years, proved good.

Excellent Champagne has been made from British grapes for a shilling per bottle, and it is said that foreign grapes are now imported for this purpose.

SUBSECT. 2.—*Raisin Wine.*

3459. *Since raisins are dried grapes, there appears no reason why excellent wine should not be made from them*, as we know that it is found necessary to dry, wholly or in part, the grapes employed in the manufacture of the finest sweet wines of the south of Europe, as those of Cyprus, Malaga, and Tokay; and as the dryness of wines only depends upon the fermentation being continued longer, it seems obvious that, from raisins, good wines, both sweet and dry, may be easily produced in Britain. This, accordingly, is well known to be done upon an immense scale in manufactories, among which that of Beaufoy has been long celebrated; but the wines thus produced are often, by certain management, contrived to pass for foreign white wines of various denominations, instead of being sold in their genuine state. The success of individuals shows that the process of making good raisin wine is extremely easy; and any family desirous of doing so may thus supply itself with genuine wine at a very moderate price.

3460 *To make Raisin Wine.*—Procure fresh Smyrna or Malaga raisins; pick out the stalks and all defective fruit; chop twenty-eight pounds of these into small bits, and pour upon them three gallons of tolerably hot water, and let them stand to soak for twelve hours. Put the whole into a hair cloth or clean canvass bag, and with a sufficiently powerful press press out the juice. Put two gallons more of hot water on the marc of raisins; let this remain also twelve hours, and press out as before. Mix the two liquids together, but the skins are not to be used. Add to the juice thus obtained three pounds of white sugar, and put the whole into a proper vessel to ferment. Some add an ounce or two of crude tartar, but no yeast, as the raisins contain of themselves sufficient fermenting principle. This liquor will ferment, and the vessel should be covered with a blanket. When the first fermentation is over, the wine is to be transferred or racked into a clean cask, and suffered to undergo the slow fermentation; it is then to be kept bunged up for three months, and then racked into another cask. In about twelve months it will be fit to bottle. Some add brandy after the first fermentation; but this is not necessary. A still richer wine may be made by increasing the quantity of fruit, and leaving out the sugar.

3461. *Mr. Aikin, formerly secretary to the Society for the Encouragement of Arts, &c.*, made a light, dry raisin wine of excellent quality; and the following is an account of the process, abridged from his paper in the Transactions of the Society:

The raisins which he employed were the muscatel, which are imported in boxes containing about twenty pounds, and when new are in common use as a table fruit. In this state the price prohibits its employment for this purpose; but in those which remain unsold for about a year, the rich pulp of the recent raisin becomes mixed with sugary concretions, which renders them less acceptable at the dessert; and the price of such fruit, being about ten pence a pound, brings it within the reach of the domestic wine-maker. The matter contained in grapes, which we have described by the name of ferment, exists in raisins in sufficient abundance to change into wine a greater quantity of sugar than the fruit contains, and it was found advantageous to add to the raisins from one tenth to one third of their weight of sugar. In order, however, to avoid tainting the wine with the peculiar flavour of brown or moist sugar, which happens generally in the usual mode of making raisin wine, he used good loaf sugar. Having separated the raisins from the stalks, the former were chopped very fine.

The proportion of the ingredients found to be the best was three pounds of raisins, one pound of sugar, and one ale-gallon of water. The must was prepared sometimes by mashing, and sometimes by maceration.

The mashing was performed as follows: The chopped raisins being put into an open tub or earthen-ware pan, hot water was poured on them, in the proportion of about a quart to four pounds of fruit. It is desirable, in this first mash, to extract the greater part of the saccharine mucilage as little altered as possible; the water was therefore heated only to about 120°. The water and fruit, after being mixed, was suffered to stand about a quarter of an hour, and then the whole was stirred carefully by the hand, taking care to break down all the lumps. The whole was next poured upon a sieve placed over a tub, where it drained for a short time; the husks were pressed by hand, and were returned to the mash-tub. The second mash is made exactly as the first; and the husks, after pressing, are returned to the mash-tub.

The raisins were now found to have lost all their clamminess, though they were still sweet; the greater part of the saccharine mucilage had been therefore extracted, and the principal object in the subsequent mashes is to dissolve the tartar which they contain. For this purpose the water of the third mash was heated to 150° or 160°, and was managed as the former. The liquor thus obtained was in a considerable degree acidulous, from the tartar having the flavour of the raisins, and but little sweetness. Three fourths of the mash being now made, the next operation was regulated by the degree of astringency which it was wished the wine should have. If it were desired the wine should be somewhat astringent, some boiling water was poured upon the stalks of the raisins, which were kept for that purpose in a separate tub, and, after they had macerated for a quarter of an hour, the liquor so produced was poured into the third mash, and well mixed with it; if astringency was not wished for, the stalks were rejected. In a quarter of an hour the liquor was put in the sieve, and the husks were well squeezed by hand. While the last mash is preparing, the liquor of the first three mashes was transferred to the fermenting tun, and the sugar was dissolved in it; then as much of the last mash was added as was requisite to bring the must to the due proportions, viz., one ale-gallon of must to three pounds of fruit, and one pound of sugar. The time occupied by the above processes was four or five hours.

The temperature of the must, when put into the fermenting tun, was usually about 70°; and the fermentation began in from twelve to thirty-six hours, according to the weather and the manner in which it was treated. The scum which rose was sometimes taken off every day, and sometimes it was allowed to remain till the liquor was about to be removed from the fermenting tun. If the fermentation was languid, the cover of the tun was kept on, and the scum was stirred daily into the liquor; if too rapid, the cover was taken off, and the scum was removed as it rose. In general, the best time for fermenting was when the temperature of the air is from 55° to 60°; of course, cold, frosty weather is unfit. When the fermentation had become languid, and was judged to have been sufficient, the liquor was vinous, but sweet; it was then carefully skimmed, and transferred to glass carboys containing about six or seven gallons, or to stone-ware barrels of the same size. As the latter are always more or less porous, they should be warmed thoroughly before a fire, and rubbed over with a mixture of bees'-wax and turpentine (about one part of turpentine to three of bees'-wax), and when this thin coat is grown cold, it should be well rubbed in with a hard brush. Instead of the usual vent-peg, which, however, answers the purpose, though requiring more attention, a more elegant method was employed, by the use of a well-known chemical apparatus called tubes of safety, which are little bent glass tubes containing a drop or two of quicksilver; these are inserted in the bungs, which are cemented down and covered with a mixture of wax and resin. The fermentation that goes on in the cask will be distinctly shown by the motion of the quicksilver in the tubes, as the carbonic acid gas that escapes will pass through the quicksilver; and this will continue for some weeks, after which it ceases. Upon the whole, the loss by fermentation in the tun is usually about six per cent. The wine should remain in the carboy or cask an entire summer, in order that the whole of the sugar may be decomposed by the fermentation. If the wine is made in April, it is bottled in the following March: if made in October, it is bottled about the end of September, or a week or two later, according to circumstances.

The wine is never fined, Mr. Aikin being of opinion that the light dry wine, which it was his aim to produce, would be materially injured by being deprived of its tannin through the action of isinglass or any similar substance. At the time of bottling, the wine did not appear to have any very sensible flavour, meaning by flavour that compound sensation of smell and taste which characterizes the finer kind of wines; but after remaining for a year in bottle, a flavour resembling elder flowers was strongly developed, mingled generally, in a slight degree, with that of prussic acid. When the principal part of the wine in the carboy had been run off to be bottled, the remaining part was passed through a flannel filter; but notwithstanding care had been taken that the wine when bottled should be clear, though not bright, there was always more or less of flocculent matter deposited, which required the bottles to be set upright in the binn, and to be decanted with care. The wine, when first decanted, was often of a very pale yellow colour, especially if highly-flavoured; but in an hour or two it deepened more or less, and at last acquired a tint like that of Bucellas, the prussic acid flavour at the same time disappearing.

Subsect. 3.—*General Principles for the Fabrication of Domestic Wines from other Fruits independent of the Grape.*

3462. *Though the principles described for making wine from the grape are, in general, applicable to that from any other fruit*, yet, from some differences in the composition of the latter from that of grapes, certain circumstances require particular attention.

3463. *We stated that grapes alone of all our fruits contain tartaric acid united to potash*, and that this tartrate of potash, though held in solution in the fruit, being insoluble in alcohol, is precipitated in a solid form, called tartar, when fermentation has converted a portion of the must into spirit; and that, consequently, grape wine properly made is free from acid, the tartaric being the only one contained in grapes in any considerable quantity. With all our other fruits the case is different; they do not contain the tartaric acid, but, instead, they have chiefly the malic, and sometimes the acetic and the citric, all of which exist either in a free state or form salts that are soluble; hence they remain in the wine after it is made, and are, to a certain degree, injurious to the human constitution. Another circumstance which distinguishes grapes from other fruits was stated: the tartar which they contain naturally acts as a ferment in the must, and hence grape-juice ferments spontaneously; but the ferment of other fruits is in such small quantity that yeast must be added to their juices to begin the fermentation.

3464. *The art of making what is termed home-made wine in England is of no great antiquity.* Pennant says that in the year 1635 they began to make some from the raisins or dried grapes of Spain and Portugal, and that one Francis Chamberlayne had succeeded so well that he obtained a patent for the manufacture of such wines for fourteen years. The author of the "Tatler" complained that in his day "they could squeeze Bordeaux out of the sloe, and draw Champagne from an apple."

3465. *It must be evident that a knowledge of the chemical composition of all substances used in fermentation* is essential in our reasonings or experiments made to ascertain the best modes of operation. But, unfortunately, vegetable chemistry has not yet made sufficient progress, or chemists have not considered it as an object of sufficient importance, to determine with accuracy the analysis of our various native fruits. We are, therefore, enabled only to possess general ideas on this subject, which, however, imperfect as they are, will assist us in our practice. The gooseberry has been chemically examined by Dr. John; but the proportions of its ingredients were not ascertained. It consists of water, uncrystallizable sugar, bi-citrate of lime, bi-citrate of potash, bi-malate of lime, bi-malate of potash, resin, a modification of gum, fibrin, ammonia in an unknown state of combination, phosphate of lime, and phosphate of magnesia.

Whether great practical advantages would result from the complete analysis of all our fruits employed for the purpose of making wine, it is difficult to say at present; but the analogy of similar cases would lead us to desire more definite information on this subject than we yet possess.

3466. *Dr. Macculloch, in consequence of successful experiments which he has made on this subject, recommends the addition of tartar* in preparing the must of domestic wines from other fruits than grapes. He has found this not only to meliorate the quantity of the produce, but also to increase the spirit which a given quantity of sugar is capable of yielding. The same author farther observes that experiments have not determined accurately the proper proportion of tartar that should be used; but as all wine deposites tartar with its lees, it may be considered that it has dissolved as much as it can of this salt during the process of vinification; or, in other words, only a certain quantity can remain in solution in the wine, the rest being precipitated or thrown down as so much extraneous matter. It is not likely, therefore, he observes, that we should err in adding too much, as the wine will only keep its proper proportion. The proportion of tartar may vary from two to six per cent., in proportion to the sweetness of the fruit and the quantity of added sugar, the sweetest must requiring most tartar. For this purpose the purified cream of tartar may do, but this is the *pure* bi-tartrate of potash separated from the fermenting principle, which is united with it as it falls down in the lees. The crude or unpurified tartar is better, and it should be employed in the same state in which it comes from the wine casks. This will be a powerful and proper ferment, instead of the yeast commonly made use of.

3467. *The malic acid, which derives its name from its abundance in apples, is the predominant acid in our fruits*, and, indeed, constitutes the chief difference between cider and wine. It might be a question for chemists whether some means might not be contrived for getting rid of a portion of the malic acid which is so detrimental to our domestic wines. Dr. Macculloch observes that perhaps a hint might be taken from the manufacture of sherry in Spain, in which lime is added to the grapes, which probably acts in neutralizing what portion of malic acid they may contain, or a part of the tartaric acid.

3468. *With respect to the processes for producing wine from our fruits*, our readers will have perceived, from what was said on making wine from grapes, that different methods must be pursued, according to the class of wine intended to be made, and whether they are to be brisk, dry, or sweet; and that no positive rules can be given applicable to all cases.

The manner of modifying the must and the fermentation for each of these is the same as in the case of grape wine; and we need not repeat the general principles, but refer the reader to what has already been said on the subject, adding, however, a few remarks.

3469. *Wine of the brisk kind is generally made here from gooseberries*, but it may also be produced from currants, or any other fruit, care being taken not to use it too ripe, and by following the directions already given. This modification of wine is one of the most esteemed, and deservedly so, and therefore the principles for forming it ought to be carefully studied, since failure can only occur from negligence or ignorance in the conduct of the process.

Sweet wines may be made from any ripe fruit, sufficient sugar being added, and the fermentation stopped in time, not to decompose too much, which is effected by racking off the wine from the lees into a clean cask, and even to remove what still remains of the ferment by clarifying with isinglass or white of eggs.

3470. *Dry and light wines*, like Hock and Grave, have seldom been successfully produced by our domestic wine-makers, except from grapes. The reasons are chiefly that they require the saccharine matter to be completely decomposed by fermentation, as we have already explained; but this has seldom been sufficiently attended to, nor the subsequent operations of racking, sulphuring, and fining: too much sugar has also, in general, been employed, from which they have turned sour, or have remained sweet. These wines are the most difficult to fabricate, and success is unattainable except all the circumstances which we have pointed out are accurately attended to. Wines that are dry and strong, such as Madeira and sherry, are seldom attempted with our fruits; but these might also be made by increasing the proportion of sugar and ferment, if due attention be paid to every part of the processes. With respect to strength, we have already explained that the sugar must be chiefly depended upon for giving it.

3471. *In proportioning the sugar according to the desired strength of the wine*, Dr. Macculloch gives the following rules: Two pounds of sugar, added to a gallon of a compound containing all the other ingredients requisite to a perfect fermentation, produce a liquor equal in strength to the lightest class of Bordeaux white wines. Three pounds' produce are equal in strength to the wine known by the name of white Hermitage; and from four, if fermented till dry, a wine resembling in strength the stronger Sicilian wines, that of Marsala, for example, or the Cape Madeira, is produced.

3472. *One of the faults frequently occurring in our domestic wines is excessive sweetness*, arising from too large a proportion of sugar having been employed compared with that of the fruit juice, or from the imperfect fermentation which the fluid has undergone. If it arise from the first cause, it is obvious that the evil might have been avoided at first by reducing the quantity of sugar and increasing that of the ferment and tartar: if it proceed from the latter cause, the fermentation might have been prolonged.

3473. But this sweetness is often intentional, for the purpose of concealing much acidity. We have stated that the wines made from our fruits cannot be entirely freed from the acids contained in them, and that, to cover this, a superabundant sweetness is found necessary.

We are prevented from deriving all the advantage which we might from the natural sugar existing in our fruits, because, were we to depend upon fruit juice alone, we should introduce too much malic acid into our wines, no means being known for separating this easily. Hence we are obliged to add artificial sugar in the must, and to dilute it with water, that we may have sufficient spirit with as little malic acid as possible. In making currant or gooseberry wine, if the fermentation was suffered to go on till the whole of the saccharine matter was converted into alcohol, the wine would be very acid, there being then no sugar to conceal the taste. It is, therefore, necessary to arrest the process, during the progress of the fermentation, long before the whole of the saccharine matter is consumed. There is, therefore, little natural strength in such wine, and it will not keep long, for the remaining free sugar is converted into acid by the slow fermentation, and the taste of the acid is perceived. Brandy is then frequently added to increase the strength of the wine, and to retard the slow fermentative process, and, consequently, the conversion of the remaining free sugar into alcohol, and it thus hinders the wine from tasting sour so soon; but the bad effects of brandy have been already pointed out.

3474. *But it is generally prudent to have the full quantity of sugar;* for we have said that there is seldom such a balance of the two fermenting substances, the saccharine matter and the yeast, that both are perfectly neutralized, and it is not possible always to determine if this has been the case; for the palate is unable to detect a very small portion of sugar, as its taste is masked by that of the wine; and the fermenting principle is still less ascertainable by the taste. If the wine be sweet after the fermentation, it is evident that some sugar remains undecomposed, and that all the ferment has been expended. In this case the wine will not turn sour immediately, particularly if it be strong, because there is no ferment to carry it on to the acetous stage. But if the wine be light, that is, not strong, and the fermentation should have been carried on so far that the wine is *dry*, that is, not sweet, it is a proof that all the sugar has been expended; there is then great danger of its passing into the acetous state, and becoming vinegar. In this case, the addition of sugar *immediately* will prevent this change, as it will serve for the ferment to act upon; but should the acetous change have already begun, sugar will only accelerate, instead of retarding it.

3475. *Another fault in domestic wines is excessive sharpness;* and this is an accident liable to happen from the prevalence of the malic acid in our native fruits.

3476. *The proportion of water to be used in the prepared must* is of great consequence, and Dr. Macculloch reprobates the current practice of using too great a quantity, and too little juice of the fruit: a custom apparently originating in a misplaced economy. In the practice of making wine from grapes in the wine countries, no water is used, but the whole fluid is composed of the juice of the fruit itself; but in the common practice, as recommended in the English domestic receipts, the juice of the fruit rarely forms more than one third of the whole liquor, and often much less; this proportion being also fixed without regard to the ripeness of the fruit. This artificial *must*, thus compounded of water, sugar, and juice, contains, in general, too small a quantity of the fermenting principle so essential to a perfect fermentation; the fermentation is too slow, and only a small quantity of alcohol can be the result; hence the liquor is so weak that it soon changes into vinegar. When green fruit is used, in which little exists but acid and ferment, of which the former, in this case, exceeds, bulk for bulk, the quantity in ripe fruits, the acid would generally be too abundant, and would require a dilution with water. But in ripe fruits, where the acid is reduced in its proportion, there is not the same necessity for employing water, and a smaller proportion of it will be sufficient, and with advantage to the wine. If too little water is used, the juice and sugar are too much concentrated, the fermentation is brought on with difficulty, and its progress is so slow that the operator will sometimes conceive, from the time employed, that it has continued long enough when it has scarcely commenced; and the result is therefore a sweet wine, the fermentation being stopped before all the vinous fluid has been formed.

3477. *Good flavour is a very important quality in wine, and our native fruits are mostly deficient in this quality;* nor is what they do possess always of the best kind. It is frequently useful, therefore, to introduce substances for the purpose of giving agreeable flavours. Here one caution may be of use: it is not to do too much. Wine may bear a small quantity of a particular flavour with advantage, whereas an increase of the same may be even nauseous. The taste alone can here be the only guide, which must regulate experiments and practice. Various substances are employed by wine-makers with this view: flavours of elder, cowslips, clove-pinks, vines, have all been occasionally used; likewise, other flavours may be obtained from sweet-briar, wormwood, walnut leaves, oak chips, rose water, sweet and bitter almonds, ginger, cloves, and orris root. The strawberry and raspberry have a high flavour, but it is difficult to preserve them during the process of vinification, otherwise we might have highly-scented wines. The most convenient mode of managing all these is to suspend them in a linen bag from the bung-hole of the cask during fermentation; and care must be taken to taste the liquor frequently, that the flavouring ingredient may be withdrawn in time. Astringency, when required, may be communicated in the same way, by catechu and other materials containing tannin, or the astringent principle. An agreeable bitterness may be given by burned sugar, which is likewise capable of producing every variety of yellow colour that can be desired in these, as in the wines of the grape.

3478. *Colour* is a matter of little comparative moment in our domestic wines. The only fruits of our own growth capable of yielding colour are the black cherry, strawberry, black currant, raspberry, mulberry, elderberry, and blackberry; the latter also affords a very agreeable flavour. Colour, when required, may also be communicated by several dye-woods, as Brazil wood, logwood, also oak chips, burned sugar, &c. *The astringent principle* is found in the sloe and the damson; and may, if required, give a roughness like that of port; but this is seldom desirable.

3479. *We have already stated that it is necessary to add yeast* or tartar in fermenting wine made from our ordinary fruits, although grape juice ferments spontaneously; but the yeast of beer should not be employed if it can be avoided, since it contains some of the bitter of the hop. It is best, when that can be done, to employ yeast obtained from a former fermentation of wine. The lees of grape wine may be preserved for this purpose in a dried state; and the yeast of gooseberry wine keeps perfectly well dried.

3480. "*It is a prejudice not uncommon,*" Dr. Macculloch observes, "*to suppose that the wines made from the fruits of this country are unwholesome.*"

"There is no doubt that they may occasionally disagree with individuals, either from defects in their fabrication, or from their undergoing the process of decomposition from pernicious accidental admixtures, or from the idiosyncrasies of particular constitutions. But they are not necessarily unwholesome;" and he adds, that their general insalubrity, whatever it may be, will certainly be diminished by every step which they shall make in their approach to the wine of the grape, that standard of perfection to which they must all ultimately be referred. But we should observe, that Dr. Macculloch in this alludes to domestic wines made by private individuals in the best manner, and not to what is sold in shops, of the manufacture of which we are ignorant.

3481. *With respect to the wholesomeness of our domestic wines made from ordinary fruit,* as they are commonly manufactured and sold, we cannot recommend them, considering the quantity of free acid which they usually contain, and that their actual composition is not known to us; and though, by proper management, conducted upon principle, they may be made by private individuals of superior quality, yet we are far from holding out the hope that they shall, from our native fruits alone, independently of the grape, ever be the rivals of the wines of foreign countries. But, without pretending to do with our gooseberries, currants, and other fruits of that kind, what is impossible, we might fairly expect to make from them a class of useful beverages, as various, at least, as the fruits from which they are produced, and holding an intermediate rank between the more ordinary ones, cider and perry, and that first of all liquors, the wine of the grape.

3482. *The usual addition of brandy to our domestic wines* is a circumstance that deserves particular consideration. We have stated that the great radical defect in this manufacture is using too small a quantity of fruit compared with the sugar employed. It is this circumstance chiefly which renders the fermentative process incomplete, and thus imparts the sweet, mawkish taste which renders our wines intolerable to most people, and even to all, perhaps, without the addition of brandy. We have, when treating of "Foreign Wines," stated the great prevalence of this practice in preparing many wines for the English market, and the bad effects of it. The general taste of this country, so long accustomed to strong brandied wines, can scarcely relish less potent beverages; but the alleged reason for introducing spirits into our domestic wines is that without it they will not keep; but it has been shown by Dr. Macculloch that the necessity of introducing spirits into our wines on this account is a mistaken notion; and that, were they made with the proper quantities of the materials, and with due attention to the fermentation and other processes, there is no reason why our wines should not be sufficiently durable without this addition. Independently of the brandy never combining completely with the wine, and, consequently, existing in a state that renders it injurious as a beverage, *fine* wines are invariably spoiled by the addition of ardent spirits, which seems to have the effect of slowly decomposing them, and thus of destroying that delicate, brisk, and lively flavour so eminently possessed by natural wines. If the addition of brandy be thought essential, either for keeping or strength, it should be done during the second fermentation in the cask, or the fretting-in process, since then a portion, at least, of the spirit will enter into permanent combination with the wine, which will not be the case when the fermentation is completed.

3483. *The names of foreign wines given to our home manufactures by dealers* is a gross fraud upon the public, and is particularly calculated to mislead numerous persons little acquainted with the history of wines, and who scarcely know that Calcavella, Frontignac, and other names displayed in a conspicuous manner in our shops, belong to wines of the Continent which cannot possibly be made in Britain. There is nothing wrong in endeavouring to imitate the flavour of these wines; the crime is in not taking care lest the purchaser should lie under the erroneous impression that the imitation is the original wine. Another circumstance is obvious; that, as we do not know all the substances employed in making these imitations, not having any acquaintance with the chemical skill nor the honesty of those who manufacture them, we run the greatest risk, if not of being actually poisoned, yet of taking substances in our wine extremely deleterious to our health. Nothing is more dangerous than permitting the composition of our food or drink to be a secret; and it must be evident that it has been a leading idea, all through this work, to enlighten the public upon this subject, and to induce every one to perceive the necessity of understanding accurately the nature of what is so important to our health, and, consequently, our happiness. Those who are desirous of ascertaining how nearly our domestic wines may be made to imitate those of foreign growth will be safe if they make the trials themselves, guided by their own skill in chemistry, or that of some chemical friend; and experiments of this kind, conducted with care, will highly deserve being laid before the public. We would strongly recommend all those who turn their attention to the subject to possess themselves of the theoretical principles which we have endeavoured to render familiar and easy to be comprehended, as this cannot fail to light them in their path in making experiments and trials in making wine. Some knowledge of the elements of chemistry will be of the greatest use in enabling them to vary their practice as circumstances may require.

3484. *We have now given a sketch of the leading facts which are necessary to be known in the art of making domestic wines; but as we are convinced that there are many persons who will not take the trouble of studying these with sufficient attention,* who yet would be desirous of attempting to fabricate some home-made wines in the usual manner by following a receipt, we feel it necessary to add *some receipts of this kind,* collected from the best sources.

SUBSECT. 4.—*Gooseberry Wine.*

3485. The gooseberry is one of our fruits most commonly used among us for domestic wine, and, if managed judiciously, may produce an excellent brisk wine, which is likewise the readiest made, and the cheapest. For this purpose the fruit may be used in the unripe state; and wine so prepared, by judicious management, comes often so near to real Champagne as not to be distinguished except by those much accustomed to the French wine. It is difficult, however, to get quite rid of a peculiar flavour derived from the gooseberry, which is most developed in the ripe fruit, and is less perceptible in the immature state. This flavour resides in the skins alone, and therefore some employ the expressed juice only; but it must be observed that the produce is thus rendered nearly tasteless, which, however, is not so bad as an offensive flavour; but a certain proportion of the skins is observed not to injure, but to communicate a flavour that is rather agreeable.

3486. Various proportions of fruit and sugar are given in different receipts; but Dr. Macculloch observes that the quantity of fruit is usually too small, and the fermentation is generally so imperfect that the wine is left disagreeably sweet.

3487. From the ripe gooseberries having more saccharine matter, sweet and dry wines may be produced; but these are ill flavoured, particularly if the husk is not carefully excluded, which contains more flavouring substance in proportion to its ripeness.

Gooseberry wine, properly made, is perfectly durable, as much so as Champagne of corresponding strength, provided equal care be taken in the bottling, cellarage, and other management, all of these being circumstances in which our domestic fabricators are too apt to fail.

3488. *Dr. Macculloch's Receipt for making Gooseberry Wine.*—"The fruit must be selected before it has shown the least tendency to ripen, but about the time when it has nearly attained its full growth. The particular variety of gooseberry is perhaps indifferent; but it will be advisable to avoid the use of those which in their ripe state have the highest flavour. The *green Bath* is perhaps among the best. The smallest should be separated by a sieve properly adapted to this purpose, and any unsound or bruised fruit rejected, while the remains of the blossom and the fruit-stalk should be removed by friction or other means. Forty pounds of such fruit are then to be introduced into a tub carefully cleaned, and of the capacity of fifteen or twenty gallons, in which it is to be bruised, in successive proportions, by a pressure sufficient to burst the berries, without breaking the seeds or materially compressing the skins. Four gallons of water are then to be poured into the vessel, and the contents are to be carefully stirred and squeezed in the hand until the whole of the juice and pulp are separated from the solid matters. The materials are then to remain at rest from six to twenty-four hours, when they are to be strained through a coarse bag by as much force as can conveniently be applied to them. One gallon of fresh water may afterward be passed through the *marc*, for the purpose of removing any soluble matter which may have remained behind. Thirty or twenty-five pounds of white sugar are now to be dissolved in the juice thus procured, and the total bulk of the fluid made up with water, to the amount of ten gallons and a half. If I name two quantities, it is because the fruit itself varies in quality, and it depends on the operator to distinguish. The old receipts allow forty pounds, of which the consequence is, invariably, a sweet wine, while it fails of being brisk in nine out of ten cases. And the smaller proportion here given will most frequently ensure a brisk wine, if the operator will but attend to the progress of the fermentation, and the treatment as formerly described. The liquor thus obtained is the artificial *must*, which is equivalent to the juice of the grape, that is, made to resemble it as nearly as possible. It is now to be introduced into a tub of sufficient capacity, over which a blanket or similar substance, covered by a board, is to be thrown, the vessel being placed in a temperature varying from 55° to 60° of Fahrenheit's thermometer. Here it may remain for twelve or twenty-four hours, according to the symptoms of fermentation which it may show, and from this tub it is to be drawn off into the cask in which it is to ferment. When in the cask it must be filled nearly to the bung-hole, that the scum which arises may thrown out. As the fermentation proceeds, and the bulk of the liquor in the cask diminishes, the superfluous portion of *must*, which was made for this express purpose, must be poured in, so as to keep the liquor still near the bung-hole. When the fermentation becomes a little more languid, as may be known by a diminution of the hissing noise, the bung is to be driven in, and a hole bored by its side, into which a wooden peg, called the *spile*, is to be fitted. After a few days this peg is to be loosened, that, if any material quantity of air has been generated, it may have vent. The same trial must be made after successive intervals, and when there appears no longer any danger of extensive expansion, the spile may be permanently tightened.

"The wine thus made must remain over the winter in a cool cellar, as it is no longer necessary to provoke the fermenting process. If the operator is not inclined to bestow any farther labour or expense on it, it may be examined in some clear and cold day towards the end of February or beginning of March, when, if fine, as it will sometimes be, it may be bottled without farther precautions. To ensure its fineness, however, it is a better practice to decant it, towards the end of December, into a fresh cask, so as to clear it from the first lees. At this time, also, the operator will be able to determine whether it is not too sweet for his views. In this case, instead of decanting it, he will stir up the lees so as to renew the fermenting process, taking care also to increase the temperature at the same time. At whatever time the wine has been decanted, it is to be fined in the usual way with isinglass. Sometimes it is found expedient to decant it a second time into a fresh cask, and again to repeat the operation of fining. All these removals should be made in clear, dry, and, if possible, cold weather. In any case it must be bottled during the month of March. The wine thus produced will generally be brisk, and similar in its qualities (flavour excepted) to the wines of Champagne, with the strength of the best Sillery, if the larger proportions of sugar have been used, but resembling the inferior kinds with the smaller allowance. Inattention, or circumstances which cannot always be controlled, will sometimes cause it to be sweet and still, at other times, to be dry. In the former case it may be manufactured the following season, by adding to it that proportion of juice from fresh fruit which the operator's judgment may dictate, and renewing the fermentation and subsequent treatment as before. In the latter case, as its briskness can never be restored, it must be treated as dry wine by decanting into a sulphured cask, when it must be fined and bottled in the usual manner. Such dry wines are occasionally disagreeable to the taste in the first or second year, but are much improved by keeping; nor ought they to be drunk under five or six years."

3489. On comparing this receipt with others, it may be proper to remark that white sugar is recommended, whereas some use raw sugar, which is much inferior. Here the fermentation is performed in the cask; others ferment in an open tub for several days, thus losing much carbonic acid, skimming off the yeast as it forms; they then put the liquor into a cask, where the fermentation is renewed, the yeast which runs out at the bung-hole being cleared away as it rises. When this fermentation has ceased, they add brandy, and sometimes honey, a practice which is condemned by Dr. Macculloch.

3490. *Mr. Donovan's Process for making Wine from ripe Gooseberries.*—"Although the fruit should have been red, the wine will not be so; its tint will be a flesh colour, for the red colouring matter is precipitated during the process. The wine will not be quite so good as that from unripe fruit, at least it will require a far longer time to ameliorate to the same degree of goodness. Ten gallons of gooseberries are to be bruised in a tub, and left so for twenty-four hours. The pulp thus prepared is to be introduced, either at once or in successive portions, into a hair cloth or canvass bag, and submitted to pressure. The matter remaining in the bag is to be returned into the tub, and five gallons of tolerably hot water are to be poured on: the whole is to be well mixed up. After thus remaining in the tub well covered for about twelve hours, the matter is to be pressed through the bag, and the liquor obtained is to be mixed with the original juice. The solid matter of the fruit is then worth very little, and may be thrown away.

"In every five gallons of the liquor, consisting of the mixture of the original juice with the infusion, twelve pounds of white sugar are to be dissolved perfectly. If the liquor be now left to itself, it will, after some hours, show symptoms of a commencing fermentation. In proportion as the fruit is ripe, the temperature of the weather ought to be high. Should it be very cool weather, the liquor should be placed near the fire. If the gooseberries were unripe, or just ripening, the fermentation will take place at a lower temperature, and with more activity.

"The progress of the fermentation should be frequently ascertained by tasting the liquid, it becoming continually less sweet until at length the sweetness totally disappears; at this period the fermentation is complete. When the fruit has been over ripe, or when the weather is remarkably cool, the last portions of sugar remain a long time unaltered, and the fermentation is suspended. Placing the containing vessel near the fire will always renew the fermentation; so long as this degree of heat is kept up the fermentation will proceed. When the quantity of wine under fermentation is very considerable, it will generally keep up its own temperature. Should the season be so warm, and the fermentation so rapid, as to excite fears of souring, which, however, can never happen while the quantity is so small as ten or twenty gallons in each fermenting tub, we can readily avert the danger by racking off from the lees, having first skimmed off the head of yeast.

"When the fermentation has totally ceased, the wine is to be racked off as clear as it can be procured. To every five gallons of it two quarts of brandy or good old malt spirit are to be added, well mixed and left to settle; for the spirit causes a separation of flocks which previously had been in solution. After subsidence for perhaps a month, the clear liquor is to be cautiously drawn off, introduced into a cask which it just fills, and set by in a cool cellar for a great length of time. It is seldom that the impatience and curiosity of inexperienced makers of domestic wines for family use can brook the delay of keeping the wine long enough to mellow sufficiently. The wine just described will require five years at least to be in its best condition, and must have been kept in wood all that time; it may then be bottled. A much shorter time will, however, render it tolerable."

Subsect. 5.—*Currant Wine.*

3491. *Three varieties of currants are employed in making wine*, white, red, and black, but the first two are most common. The wines from the white and red sorts differ a little from each other in colour, and also in flavour. With proper management, they are capable of producing a wine analogous to the lighter wines of the grape, according to Dr. Macculloch, "not easily to be distinguished from the Colares of Portugal, which, although not in the first class, is certainly superior to most of our domestic wines." A principal defect in currant wine, as commonly made, arises from too small a quantity of the fruit being used, and, of course, too much sugar and water. On this account, and from the imperfect fermentation, these wines are usually too sweet, and from a natural bad flavour in the husks, which are often kept in the *must*, a mawkish taste is induced. By increasing the quantity of fruit, which is generally used only in the same proportion as in gooseberry wine, and avoiding the use of the husks, the flavour and quality of the wine are materially improved.

At present only sweet wines are generally made from currants; but dry wines may also be fabricated from this fruit by the methods already pointed out; for these the fruit should be ripe.

Brisk wine may also be made, and then a proportion of unripe fruit should be introduced. The use of tartar, likewise, Dr. Macculloch is of opinion, would be advantageous, and would correct a defect not uncommon, that of having an ammoniacal taste.

Another improvement has been put in practice with success, not only in making currant wine, but in all those wines produced from fruits of which the flavour is either bad, or which have little or no flavour; this is *by boiling the fruit juice* previously to fermentation. From this treatment many tasteless fruits acquire a flavour, and many bad flavours are converted into agreeable ones. This is particularly remarkable in the case of the black currant, which, though harsh in its natural state, acquires by boiling a powerful and, to most persons, an agreeable flavour. Wine made from this fruit in the raw state has no particular property, whereas that of the boiled may be, by careful management, brought to resemble some of the best of the sweet Cape wines. The boiling must not be too long continued, as this degree of heat tends to coagulate and precipitate the ferment, and thus render it ineffective. Some artificial ferment is generally necessary with boiled juice. Great care must be taken in separating the stalks; and if the skins and solid matter are fermented in the vat, they must not, at all events, be introduced into the casks. Many persons put the pure juice into the casks at once, strained, without any previous fermentation in the vat.

Receipt for White Currant Wine.—Bruise forty pounds of fruit in a tub of the capacity of fifteen or twenty gallons, and add to it four gallons of water. Stir the whole well, and squeeze till the pulp is thoroughly separated from the skins. Leave these materials at rest for about twelve hours, and then strain them through a canvass bag or fine hair sieve, and pass one gallon of fresh water through the *marc*. Dissolve thirty or twenty-five pounds of white sugar in the juice thus obtained, and make up the whole quantity by an addition of ten gallons and a half of water. The proportion of sugar here given is for a brisk wine; if a sweet wine is required, there must be forty pounds of sugar. White sugar is recommended as much the best; if moist sugar be used, somewhat more will be necessary. The must being now prepared, the fermentation and subsequent treatment must be exactly the same as for gooseberry wine, and the reader may therefore refer to that receipt.

If brandy is to be added, it should be added towards the end of the fermentation in the cask. For the above quantity, some will put in a quart of brandy alone; others first mix it with honey.

Whether the wine should be racked off from the lees at the end of six months, put into a fresh cask for six months longer before it is bottled, or be suffered to remain the whole time in the lees, must depend upon the state of the wine, according to the principles explained above. The bottling should be carefully attended to.

Another Receipt.—White currants, nine gallons; white gooseberries, one gallon; white sugar, twenty-five pounds; white tartar, an ounce; bitter almonds, two ounces; water, nine gallons; brandy, one gallon.

3492. *Mr. Cornell's Receipt for making Red Currant Wine.*—Bruise eight gallons of red currants with one quart of raspberries. Press out the juice, and to the residuum, after pressure, add eleven gallons of cold water. Add two pounds of beet root, sliced as thin as possible, to give colour, and let them infuse, with frequent mixture, for twelve hours; then press out the liquor as before, and add it to the juice. Next dissolve twenty pounds of raw sugar in the mixed liquor, and three ounces of red tartar in fine powder. In some hours the fermentation will commence, which is to be managed according to the details given for gooseberry wine, and the principles we have stated previously. When the fermentation is completely over add one gallon of brandy; let the wine stand for a week, then rack off, and let it stand for two months. It may now be finally racked off, bunged up in the cask, and set by in a cool cellar for as many years as may be required to ameliorate it.

3493. *Black currant wine* may be made in the same manner, using six gallons of black currants, three gallons of strawberries, twenty-five pounds of raw sugar, four ounces of red tartar, ten gallons of cold water, and three quarts of brandy.

SUBSECT. 6.—*Elderberry Wine.*

3494. *The elderberry is well adapted for the production of wine.* Its juice contains a considerable portion of the principle necessary for a vigorous fermentation, and its beautiful colour communicates a rich tint to the wine made from it. It is, however, deficient in sweetness, and therefore demands an addition of sugar.

There are several methods of making this wine. The following are some of the most approved receipts:

3495. Take one gallon of ripe elderberries and one quart of damsons or sloes for every two gallons of wine to be made. Boil the fruit in about half the quantity of water till they burst, breaking them frequently with a stick. Strain the liquor, and return it to the copper. To produce eighteen gallons of wine, twenty gallons of this liquor are necessary; and for whatever quantity the liquor falls short of this, water must be added to make up. Boil this together with fifty-six lbs. of coarse, moist sugar for half an hour, and it is to be fermented in the usual manner when sufficiently cooled, and then it is to be tunned, or put into the cask. Put now into a muslin bag a pound and a half of ginger bruised, a pound of allspice, two ounces of cinnamon, and four or six ounces of hops; suspend the bag with the spice in the cask by a string not long enough to let it touch the bottom; let the liquor work in the cask for a fortnight, and fill up in the usual manner. The wine will be fit to tap in two months, and is not improved by keeping, like many other wines. Elderberries alone may be used.

3496. *Another Method.*—Elderberries, ten gallons; water, ten gallons; white sugar, forty-five pounds; red tartar, eight ounces; fermented with yeast in the usual manner. When in the cask, ginger root sliced or allspice, four ounces; bitter almonds, three ounces, suspended in a bag, may be allowed to infuse in the liquor when it is fermenting; they are then to be removed. Brandy may be added or not. When the wine is clear, which will be in about three months, it may be drawn off from the lees and bottled. The spices may be varied according to taste.

SUBSECT. 7.—*Cherry Wine.*

3497. *An excellent Wine may be made from Cherries.*—Pick Morello cherries, not over ripe, from their stalks; mash them in a mortar and pan to detach the pulp without bruising the stones, and suffer the mass to stand twenty-four hours. Press the pulp through a coarse hair sieve, and to every three gallons add from eight to nine pounds of loaf sugar. Put the mixture into a cask, add yeast, and suffer it to ferment; then rack the wine from its lees as soon as it becomes clear. Some persons crack the stones, and hang them with the bruised kernels in a bag suspended from the bung-hole in the cask during the fermentation of the wine, which thus acquires a nutty flavour. Mr. Tooke informs us that they make a good deal of this wine in Russia, and that they add some honey to the cherries.

3498. *Damson, or Black Cherry Wine.*—Infuse together for twenty-four hours eight gallons of the fruit, eleven gallons of warm water, thirty pounds of sugar, six ounces of red tartar, breaking the fruit as in the case of the elderberries. Break one eighth part of the cherry-stones, and add them to the marc. Strain and ferment as usual. The rest of the process as in currant wine.

3499. *French Method of making Cherry Wine.*—Bruise together fifteen pounds of cherries not quite ripe, and two of currants; add two thirds of the cherry kernels. Put the whole in a small cask, with a quarter of a pound of sugar to each quart of juice. Let the cask stand in sand, and cover the bung lightly while it is working, which will occupy nearly three weeks. The cask should be of the size just to hold the juice, or the latter must be made up in the above proportions to the size of the cask, as it is necessary it should be full. Carry on the fermentation in the usual manner, as in grape or gooseberry wine. When the fermentation is over, bung up the cask, and in about two months the wine will be fit to be drawn off and bottled.

SUBSECT. 8.—*Mulberry Wine.*

3500. Gather the mulberries before they are quite ripe, bruise them in a tub, and to every quart of the bruised berries put the same quantity of water. Let the mixture stand for twenty-four hours, and then strain it through a coarse sieve; having added to every gallon of the diluted juice three or four pounds of sugar, allow it to ferment in the usual manner; when fine in the cask, bottle it.

SUBSECT. 9.—*Apricot Wine.*

3501. Take apricots when nearly ripe, remove the stones, and bruise the pulp in a mortar. To eight pounds of the pulp add a quart of water; allow the mixture to stand for twenty-four hours, and then squeeze out the juice; add to every gallon of it two pounds of loaf sugar; put it into a cask and ferment it, and when perfectly clear bottle it. *Peach wine* may be made in a similar manner.

SUBSECT. 10.—*Strawberry or Raspberry Wine.*

3502. Bruise and press out the juice of either fruits. Pour on the marc seven gallons of water; infuse for twelve hours, and press out the liquor; add this liquor to the juice, and mix them with six gallons of cider. Dissolve in the mixture sixteen pounds of raw sugar, and three ounces of powdered red tartar, and then set it to ferment in the usual manner. Pare the rinds of two lemons and of two oranges, and, together with the juice, throw them into the fermenting tub, and take out the rinds when the fermentation is over. Three gallons of brandy may be added. In making raspberry wine a gallon of red and white currant juice should be added, and an equal quantity of water left out.

SUBSECT. 11.—*Cider White Wine.*

3503. Mix sixteen gallons of apple juice, sixteen pounds of honey, four ounces of white tartar; enclose in a bag one ounce each of cinnamon, cloves, and mace, and suspend it in the mixture while fermenting. When the fermentation is complete, add one gallon of rum.

SUBSECT. 12.—*Cowslip Wine.*

3504. Boil together seven pounds of moist sugar, two gallons and a half of water, and two ounces of hops. Pare the rinds of eight lemons or Seville oranges, or a part of each; pour the boiling liquor over them; when this is cool, squeeze the juice over it, and add this to the liquor. Ferment the whole with yeast in the usual way, and put it into the cask. Gather cowslip flowers on a fine day, picking out carefully all stalks and leaves. Put into the cask of wine as much of the flowers as would be a quart, when fresh gathered, for each gallon; stir them well till they sink. Dissolve three ounces of isinglass in a little of the wine, and return it to the rest to fine; in a few days bung it up close. In six months the wine will be fit to bottle, but will improve by being kept longer in the cask. By managing as above, the wine will be fined in the casks, and will be as good from the cask as if bottled, which is a great saving of trouble. The cowslip flowers may be dried and kept in bags till they are wanted, and will do as well as fresh.

SUBSECT. 13.—*Orange Wine.*

3505. Seville oranges are used for this purpose; they are best in March. For eighteen gallons of wine half a chest of oranges are required. Pare the rinds from about a dozen or two dozen, as more or less of the bitter will be agreeable; pour over this a quart or two of boiling water, and after letting this stand for twelve hours, strain off the water which extracted much of the essential oil of the oranges. Take the peel off entirely from the remainder of the oranges, squeeze the juice through a bag or a sieve, and put it into a cask with about forty five pounds of white sugar, or fifty-five of the best moist sugar. Soak the pulp in water for twenty-four hours, and after straining this, add it to the cask. Repeat this several times till the cask is full; stir the whole well with a stick till the sugar is dissolved; then set it to ferment. The fermentation is slower than with currant wine, but may be heard hissing for several weeks; when this subsides, close the bung-hole, and proceed as in the case of gooseberry wine. Some add brandy. The wine requires to be kept in the cask a year before it is bottled.

SUBSECT. 14.—*Birch Wine.*

3506. A wine was formerly made from the sap of the birch tree, though now it is scarcely known. The sap contains so much saccharine matter as to be fermented; it is to be obtained in the month of March, when it begins to ascend, by boring a hole in each tree about a foot from the ground, large enough to admit a faucet, which is to be inserted. The sap will flow for several days into a vessel placed to receive it without injuring the tree. Having obtained as much as is proper, the hole should be stopped with a peg. To a gallon of this sap add a quart of honey, or two pounds and a half of sugar, and boil them together, stirring the whole; add also two ounces of hops for every nine gallons, a few cloves, and a rind or two of lemons. Ferment this with yeast, transfer it to the cask, refine it with isinglass, and proceed as in the other cases. In about two months the wine may be bottled, and in two months more it will be fit for use. It will improve by keeping.

Birch wine has been made from an open grove of about 100 *birch trees, near Overton Hall,* for sixty or seventy years past. Thirty trees or more are tapped in a season, about six or eight inches above the ground, in March. A piece of bark about three quarters of an inch in diameter is cut out with a gouge, and the wood penetrated an inch or more; an iron spout is then driven into the bark below the hole, which conducts the sap to a bottle. In warm weather the holes soon grow up, and will cease to run in four or five days; but in windy weather they will run for a month. Some trees will run twenty-four gallons in twenty-four hours; others not half a pint. The juice is sold at sixpence a gallon to those who make small wine as a substitute for small beer. If the juice is scalded, but not boiled, it may be kept a month before it is made into wine: if not, it will not keep above a day or two. For making wine, two pounds of coarse sugar, and a quarter of a pound of Malaga raisins, are added to every gallon of birch juice when cold; it is then boiled for an hour, until it is observed to grow clearer, when it is set to cool; and when about the same heat that beer is set to work, a toast of bread, spread with yeast, is put into it, and for four days suffered to work freely, when it is barrelled; and the same quantity of raisins as before, and about an ounce of isinglass to every twenty gallons, are added. It seldom works out of the barrel, and in two or three weeks is ready for close bunging down, to remain for three months, when it should be bottled off, and in two or three weeks after it is fit for drinking, but is better for being kept longer.—*Loudon's Encyclopædia of Agriculture.*

3507. The sap of the birch is convertible into wine, vinegar, and spirit, and from it sugar may be obtained. From a large tree tapped in the spring several gallons of saccharine sap may be drawn daily without obvious injury to the plant, which forms, when fresh, an agreeable beverage, and, when fermented, an intoxicating liquor.—*Burnett's Botany.*

SUBSECT. 15.—*Ginger Wine.*

3508. Dissolve eighteen or twenty pounds of sugar in nine and a half gallons of boiling water, and add to it ten or twelve ounces of bruised ginger root. Boil the mixture for about a quarter of an hour, and, when nearly cold, add to it half a pint of yeast, and pour it into a cask to ferment, taking care to fill the cask from time to time with the surplus of the liquor made for that purpose. When the fermentation ceases, rack off the wine, and bottle it when transparent. It is a common practice to boil the outer rind of a few lemons together with the ginger destined for the wine, to impart to the wine the flavour of lemon peel.

SUBSECT. 16.—*Rhubarb Wine.*

3509. The leaf-stalks of the giant rhubarb, cut into pieces as if for tarts, and bruised with a wooden mallet to express the juice, will make a delicious wine, quite equal to green gooseberry, and very closely resembling Champagne.—*Gardener's Magazine.*

SUBSECT. 17.—*Wine made from mixed Fruits.*

3510. Take cherries, black currants, white currants, and raspberries, of each an equal quantity, though, if the black currants predominate, the better. To four pounds of the mixed fruit, well bruised, put one gallon of water; let it steep three days and nights in an open vessel, frequently stirring up the mass; then stir it through a hair sieve; put both liquids together, and in each gallon of the liquid put three pounds of sugar. Let the whole stand again three days and three nights, frequently stirring it up as before, after skimming off the top; then turn it into a cask, and let it remain at the bung-hole, while fermenting, about two weeks. Lastly, to every nine gallons put one quart of good brandy, and then fasten down the bung; if it does not soon become fine, a solution of isinglass may be stirred into the wine.—*Papers of the Bath Society,* vol. xi.

SECT. IV.—MANAGEMENT OF THE WINE-CELLAR.

To manage wines in the cellar with advantage, it is necessary to be acquainted with their manufacture, which we have already explained; also to know the several diseases to which they are liable, and the remedies.

SUBSECT. 1—*Construction of the Wine-cellar.*

It is necessary that the temperature of wine-cellars should be as uniform as possible. If liable to be affected by the variations of weather, wine in bottles will become turbid, or "sicken;" they should be placed so as not to be affected by any of the ordinary causes of concussion. Wine is easily acted upon by any unusual kind of motion; and it has sometimes happened that when taken from a good cellar in London to a bad cellar in the country it has been all spoiled.

The openings of a wine-celler ought to be few and narrow; yet the means of occasional ventilation should be provided for; but a current of air should not pass constantly through it, since this must often introduce a change of temperature.

Cellars where wine is kept in the wood should neither be too humid nor too dry. The excess of humidity may be observed by the moisture of paper, corks, &c., kept in them for some time. If the cellar is too damp, the casks are apt to rot and decay; and fungous matter and mouldiness will grow and infect the air; at the same time a moderate degree of humidity is proper; for if a cellar be too dry, the staves of the cask will shrink and warp, and occasion a loss of wine.

3511. *Different wines require different qualities in a cellar to be preserved in the best manner.* In England it is useful to have two wine-cellars, or two divisions in one, in large establishments, to suit various sorts of wine. One of these should be some degrees warmer than the other, for there are many wines which do best in a cellar of higher temperature than usual; thus Madeira, Sherry, Canary, Malaga, Syracuse, Alicant, Cyprus, and some others, keep better in warm than cold cellars, although such are not well adapted to the delicate wines of France. Where there are two cellars of different temperatures, they should not communicate, lest the temperature of each should be affected by opening the door of communication.

In cellars which hold the wines of the south it may be necessary sometimes to introduce artificial heat; and to regulate this, a thermometer should be kept in it. The increase of temperature may be obtained occasionally by a chafing-dish and charcoal, but much better by a fire, for which reason such cellar ought to be provided with a fireplace. But it should be recollected that charcoal burned in a place having no means of ventilation will render it dangerous to enter after a certain time, from the carbonic acid generated; a fireplace will be free from this danger.

3512. *The cellar ought to be swept often, and kept extremely clean,* as filth gives rise to noxious vapours, which will, sooner or later, affect the wine.

3513. *To make a cellar complete,* it should have a small ante-room, the door of which may be shut before that of the cellar is opened, to prevent, as much as possible, any change of temperature. This ante-room may be usefully employed in holding a number of things that might litter the cellar, which should be kept as free as possible from lumber.

Subsect. 2.—*Casks for Wine.*

3514. *New casks require some preparation* before wine is put into them. It is recommended that they should first be well washed with cold water. Then a hot solution of salt in water (about half a pound of salt to every thirty gallons) should be thrown in, and the cask bunged up: after this it should be well shaken, and suffered to get cold. Some wine heated should next be poured in, and the cask shaken again.

When a cask is emptied it should be well drained, and a brimstone match about an inch square burned in it; then it should be bunged up quickly and put into a dry place, particularly if not wanted for immediate use; this will prevent its contracting any bad taste.

When casks that are crusted interiorly with lees are to be rinsed, the crust may be loosened by suspending a piece of iron chain from the bung-hole and shaking the cask so that the chain may knock against the sides. Mouldiness is best destroyed by rinsing the cask with water in which quicklime has been dissolved.

The casks in a cellar should be inspected very frequently, once a month at least, that accidents may be immediately repaired. When the wine is perceived escaping from the giving way of a hoop, no time should be lost in surrounding it with an iron hoop; and in default of such a hoop, a strong rope may be used, and drawn tight round it with a packing stick, till a hoop can be got ready. Slight leakages may be stopped for a time with a little tallow or cement; but if the leakage is considerable, the wine had better be racked off into a sound cask.

3515. *The casks should be placed upon strong, elevated tressels, touching no part of the walls;* and they should, if possible, be at such a distance from the wall, that one may be able to go round them to examine the condition of the cask. When they stand near the walls they are apt to be attacked by the dry rot, and then the casks burst, and the wine is lost. They should be kept steady with wedges. Wines in wood generally ferment more or less about the time of the equinoxes, when the weather is very unsettled; and then they exert such a force upon the staves that they are apt to burst, particularly if any stave happens to be decayed: to prevent this, a gimlet hole should be bored in the bung, and stopped with a peg, to be drawn out occasionally to give vent to the gas. The casks should be filled up monthly, to make up for the loss by evaporation, or mouldiness will come over the surface of the wine and spoil it.

3516. *The binns to hold the bottles* are in some cellars made of brick-work; in others of wood, which is apt to decay; and in others they are of cast iron, and moveable, which is very convenient. The bottles should be placed in rows upon each other; some put laths between each row, to prevent one from touching the other, which might occasion breakage. The lowest row should be very well bedded upon sand or sawdust, though some omit this; and it is necessary to take care that the bottles are placed quite horizontally; for if the neck be higher than the bottom, the cork will be left to dry, and cease to close well; if lower, the lees, which continue to form, will mix with the liquid when used.

Subsect. 3.—*Racking.*

3517. *Racking is transferring wine into another cask;* this process requires sometimes to be performed in the manufacture of the wine, as has been already shown; and it is often necessary in the cellar to put an end to any fermentation that may have begun; and it is also necessary previous to a cask of wine being removed. Should the fermentation, from any cause, be renewed in the cellar, there is great danger of its passing into the first stage of acetification, or, according to the coopers' phrase, of being *pricked.*

For racking, it is proper to choose dry, cold weather, as it is then only that the wines are clear. They are frequently turbid in damp, close weather, and in southerly winds; and it is evident that if they are then racked, a portion of the thick matter will come off with the liquor.

The mode in which this operation is performed is very necessary to be known. By the common method of tapping it is scarcely possible to draw off the wine without mixing a portion of the lees with it; and the wine is much injured by being so much exposed to the air. A siphon introduced at the bung does it very effectually if well managed. An excellent method, much used in France, is one similar to that which is practised by the retailers of porter here in drawing that liquor, namely, the condensation of air on its surface. This may be readily performed without the aid of complicated machinery. To effect it, a straight brass tap, with a key to turn like a cock, is fixed in the full cask, *a, fig.* 563, three or four inches above the bottom, according to the

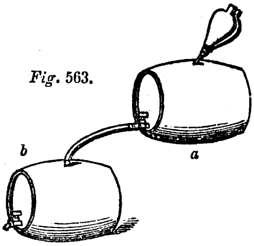

Fig. 563.

quantity of the lees. A leathern hose, three or four feet long, is provided, terminated by two tubes in a conical form to fit the brass tap. Fit one of these tubes into the orifice of the tap, and the other into the bung-hole of the empty cask, *b*. Some small holes must be bored in the highest stave of the empty cask; and fit the nozzle of a pair of common bellows in the bung-hole of the full cask. Turn the key of the brass tap so as to permit the wine to flow, and by the action of the bellows it will pass through the hose into the empty cask; by this means the wine will be transferred from one cask to the other without in the least disturbing the sediment. When all the wine has run that will pass by the hose, withdraw it, and stoop the cask to get out what more of the wine is clear. There are other methods of racking too well known to require description.

Subsect. 4.—*Sulphuring.*

3518. *Sulphuring we have mentioned as a process always employed in the preparation of sweet wines on the Continent*; and occasionally it is used here by the maker of domestic wines. Its use is to check completely any fermentation that has begun improperly, and this it will do after many other methods have failed. The explanation of its effect is the following: By the burning of sulphur, the pungent vapour produced is an acid of a gaseous nature, called sulphurous acid, which has a strong attraction for the fermenting principle in wine; and when they unite, the ferment loses its power, and becomes inactive and dead. If wine, therefore, be made to absorb in any way the vapour of burning sulphur, the ferment which it contains is effectually destroyed, and hence no future fermentation can take place in the fluid.

The manner of effecting the sulphuring is sufficiently simple. Matches dipped in sulphur are introduced into the empty cask which is to receive the wine which is to be operated upon, where they are suffered to burn as long as they will; and they will only be extinguished when they have exhausted or consumed all the atmospheric air in the cask. The vessel will then be full of sulphurous acid gas. The matches may be fixed upon a wire turned up like a hook, and fastened to the under side of the bung; after lighting them they are put into the cask, and the bung adjusted to the hole. During the burning the air expands, and escapes through a small hole bored in the bung. Great care must be taken that the match does not drop off into the cask. The wine is then poured into it, and, after being suffered to remain some time, is racked off in the usual way.

Once sulphuring is generally sufficient, but sometimes the process requires to be repeated should the ferment be very abundant; or it may happen that a slight sulphuring may be thought enough; in that case a part of the liquor only may be drawn from the cask, and a brimstone match made of rags may be held or suspended for a short time in the cask through the bung-hole, and then withdrawn. One thing should be observed, that it is said sulphuring is apt to communicate an unpleasant taste to the wine. Other substances answer the same purpose, as sulphate of potash; a drachm of this salt is sufficient for a pipe of wine, and is very useful in checking fermentation, and communicates no taste to the wine.

Subsect. 5.—*Clarifying Wines.*

3519. *Racking alone being generally insufficient to deprive wine of all its turbid matter*, a certain quantity will still remain in the liquor. *The complete clarification, which is also called Fining*, can only be effected by precipitating the turbid matter by those substances which experience has proved to possess this power. These are fish-glue or isinglass, gum, starch, rice, and albumen either in the form of white of eggs or the serum of blood. The substances most in use are isinglass and the white of eggs; whichever of these is used, it is first diluted in a portion of the wine, and then strongly agitated with the whole. After some days, when the wine has become clear, it must be again drawn off. The materials above enumerated cannot be employed indifferently for all wines: red wines are usually clarified with whites of eggs, and white wines with isinglass.

3520. *To clarify red Wines with White of Eggs.*—For a cask of one hundred and sixty bottles draw out four or five bottles; mix the whites of four new-laid eggs with half a bottle of this wine, and beat it well with some birch twigs. Put this into the cask through the bung-hole, and stir the wine well with a stick; pour in the remainder of the wine, and stir the whole again for a few minutes; replace the bung, and, after four or five days' repose, the wine will be clear and fit for bottling.

3521. *To clarify white Wines with Isinglass.*—Dissolve some isinglass in wine made lukewarm; when it is dissolved, strain it through a linen cloth, mix with it some more wine, and beat it with birch twigs. When cold, it should form a jelly. Beat some of this jelly with wine, and pour it into the cask; stir the wine about well and leave it at rest.

If, after clarifying a cask of wine, the liquid remain thick at the end of eight or ten days, take another cask, burn a sulphured match in it, transfer the wine into this, and bung up for three or four days, and then bottle it.

Subsect. 6.—*Bottling Wines.*

3522. *Bottling wine, though a simple operation, yet requires great care*, and if negligently performed, the destruction of the wine is inevitable. The first thing to be attended to is the choice of good corks: any saving in cheap and indifferent corks is false economy: it is of the first importance that they should be sound, perfectly new, well cut, and flexible; any having blackness upon them, the remains of the bark, must be rejected. As it is useful to be acquainted with the natural history of this material, we shall describe it, as well as the mode of manufacture.

3523. *Cork is the exterior bark of a tree* belonging to the genus oak (*Quercus ruber*), which grows wild in many parts of the south of Europe, particularly Spain, Portugal, and Tuscany. When the tree is about fifteen years old, its bark is fit to be stripped off, and this can be done successfully three times, allowing an interval of three years between each barking. The bark always grows up again, and its quality improves as the age of the tree increases. It is taken off in sheets or tables by making circular and longitudinal slits in the tree. As the sheets are curved when first taken off, they are flattened by heat and pressure. But there is another use in applying heat to the plates of cork. Previous to this operation the pores of the bark are open, and its sponginess of texture would make it not only give too much way to the knife, but, particularly in the case of "taps" and "bungs," would suffer the liquids to come through. The application of moderate heat causes it to shrink, and closes its pores. For this purpose the convex side is held to the fire till it is somewhat charred, which is the cause of the black colour to be seen on the surfaces of sheets of cork. In ordinary bottle corks this is not seen, because the black surface is cut away in the process of rounding them; and the pores of the cork go across from side to side of the manufactured cork, to which circumstance they owe their imperviousness to liquids. In taps and bungs this charred surface is not cut off.

The most extensive use of cork is for stoppers to bottles. To this purpose it is excellently adapted, because it is very light, may be easily compressed, and expands again by its elasticity as soon as the pressure is removed; and therefore it fills and stops up the space into which it has been driven by force. It may be easily cut into all forms, and though it abounds with pores, which is the cause of its lightness, yet these are so minute that they suffer neither water, wine, beer, nor any common liquid to escape through it, and it is but slowly, and after a considerable interval, that it can be penetrated by spirits; it is less penetrable to fluids than many hard woods, which, though apparently more compact, yet have larger pores. If corks are suspected to be bad, so as to give a corky taste, this may be prevented by dipping them completely in a varnish made of melted suet and purified wax; but in that case they should be well cemented over, likewise, to hold them down. It is the business of the cork-cutter to convert the plates into corks for use. This is effected by a sharp knife dexterously handled, and the corks are sorted, according to their qualities, into four kinds, superfine, fine, common, and coarse, which are sold at different prices. The use of cork was not unknown to the Romans; but it appears to have been more generally used after the invention of glass bottles, of which no mention occurs before the fifteenth century.

3524. *Instead of corks for bottles*, the lately invented *patent caoutchouc stoppers* are a valuable substitute. They are said to be, in the first instance, cheaper than corks, and can often be used a second time; they hermetically seal the wine, communicate no taste nor colour, and are not subject to the attacks of insects. They are formed by an extremely thin sheet of India rubber wrapped round a cylinder of elastic material.

3525. *Glass bottles*, though known to the ancients, having been discovered in Pompeii, were not in common use before the fifteenth century. Before this invention, wine was kept in vessels of earthen-ware and leather, and stoppers of wax were used. It is unnecessary to remark upon the perfection of bottles of glass on account of their transparency, which admits of seeing when they are clean, their perfect imperviousness to air, or the fluid contained in them, and their cleanness. Bottles should be selected of good manufacture, and of equal diameter throughout, or they will be liable to break in the binn when piled very high. In France, a machine is used for proving their strength before they are used. Twenty-four hours, at least, before they are filled, they should be cleaned and rinsed. Lead shot is commonly employed for cleaning them; but it is desirable that great care should be employed that none are left in the bottles, as sometimes happens; one or two grains of shot not unfrequently remain in the bottle jammed in the angle, and if these should be dissolved by the acid of the wine they will communicate to it a poisonous quality. It would be very easy to procure small, round pebble stones of the size of shot, which would answer the purpose quite as well. Sand or angular pebbles will scratch the bottles.

Bottles are best if quite new; but if thoroughly cleaned they will continue to answer sufficiently. It is much best to wash them as soon as they are empty, and to drain them by hanging with the neck downward. If they should have contracted a musty smell, they may be fumigated by a lighted brimstone match put inside, first washing them; after which, they should be washed again. In bottling, the cork should be so long in the nose as fairly to enter into the neck of the bottle to prevent spilling, or contact with the air. Nothing should be bottled that is not quite fine, and the fermentation over; otherwise the bottles may burst, particularly if they are not kept in a very cool place.

3526. *For the process of corking*, when the wine runs clear, place a shallow tub under the tap of the cask, and take care that there be two or three small holes near the bung, or in it, to allow the air to enter to supply the place of the wine drawn. All being ready, hold the bottle close under the tap in a leaning position. Fill the bottle to within two inches of the top of the neck, so that, when the cork comes in, there may remain three quarters of an inch of space between the wine and the lower end of the cork. The corks should be dipped, not soaked, in wine, and should enter with difficulty; they are driven in with a wooden mallet. If the corks are soaked all over before they are driven they are apt to shrink too much in drying, and not be tight. If the cork is to be waxed, it must be cut off close, or to less than a quarter of an inch. Champagne bottles sometimes have their corks driven but half way, and are fixed down by a wire; this makes them easy to draw. It is best to cut off the cork close to the glass, and to cover the whole top with cement, to prevent the air from passing between that and the corks. Insects also abound in some cellars, which eat through the corks.

3527. *For the cement*, resin, with half the quantity of Burgundy pitch, and a fourth of bees' wax, with a small portion of any colouring substance, is used by the French manufacturers; or, melt carefully together a pound of resin, one of bees' wax, and half a pound of tallow, and keep stirring all the while. Add to this red or yellow ochre, soot, or whiting, according to the colour required. If likely to boil over, stir with a candle end, which will check the ebullition. The end of the bottle-necks are dipped into this mixture melted.

While a cask of wine is bottling off, it is impossible to exclude the admission of air to the surface of the liquor except some particular method is employed; and if the operation last some time, the wine, especially if it be of a very delicate or superior kind, is certain to be injured. To prevent this, a method is frequently employed on the Continent which enables them to draw off the last drop in full perfection, without hurrying the bottling; and, indeed, by this method it may be drawn off slowly for drinking. A bottle of fine olive oil is poured into the cask, which, floating upon the surface of the wine, totally excludes the air, and prevents any acidity or mouldiness for a whole year. In a similar manner, the Italians preserve wine in flasks by putting a small quantity of olive oil in the necks of the flasks.

3528. *The crust, or precipitation of wine in bottles*, is only the continuation of that which began in the vat, and which is called lees, and it varies according to the species of wine, and its age, from the coarse crust of port to the *dépôt de vierre* of Champagne, or the almost invisible sediment in some other wines. This deposite consists of tartar, either red or white, and colouring matter. Those wines which deposite freely are observed to be the most durable. When they deposite much they should be decanted into fresh bottles, in case of removal, or the deposite may mix with and injure the wine.

3529. *The various operations in the cellar*, as fining, bottling, corking, sealing the wine, and placing it in the binns and entering it into a book, is the duty of the butler and his assistants. The business should be carefully arranged and divided, and the names of each sort of wine should be painted on the binn containing it to prevent mistakes.

3530. *Wine, to be fit for bottling*, must not only be separated from the gross lees, and have attained perfect clearness by fining; it must remain for a certain time in the cask to ripen, as it is called, by which its principles are more intimately combined.

3531. *The time which wine requires to be kept in wood* for its amelioration, and, consequently, the time when it is fit for bottling, differs with the character of the wine, but no precise rules can be laid down; the taste alone can determine the maturity of wines. They should not be bottled till they have lost their sharpness, and are no longer liable to fermentation. Age, therefore, is not a criterion for the excellence of all wines.

When wine is bottled too soon, it often ferments, and remains always sharp; and wine, in general, receives most benefit by remaining long in the cask before it is bottled. But though it improves likewise in the bottle, there is a limit to this term, and each variety has a period when it arrives at maturity, and when it should be drunk; after this it does not improve, but may be kept some time in the same condition, and after this it deteriorates. Some lose their strength and colour, others their fine bouquet and agreeable aroma, for which the highest class of wines are distinguished.

3532. Most of the French wines, as Champagne, Burgundy, and Medoc, are short lived; but others, having more body, will keep for a long time. White wines may be bottled, for the most part, earlier than the red, and so may the light muscadines; the latter may be bottled in a year after harvest; some of them lose their flavour by remaining longer in the cask. Light and fine wines, like those of Volney (Côte d'Or), commonly remain only a year in the cask before they are bottled.

3533. The first class of the more delicate Burgundies should be bottled at the end of the year, are in perfection when bottled two years after the vintage, and do not keep above twelve or fifteen years; but the more generous and higher coloured, such as Pomard, Vosnes, or Chambertin, should remain in the wood for four or five years, and will keep for twenty.

3534. Champagne, which requires to be bottled early, is generally in perfection the third year after bottling, and the best wines will be found to improve for ten or fifteen years, and will be sometimes good even at thirty or forty. The Rhine wines should remain in the wood for many years; the best Hock is said not to be in perfection until it is forty years old, and it will keep well four times that time. Claret should be kept seven or eight years in the wood to obtain its full quality, after which it will keep a long time in bottle. The first clarets of Maçon, however, will not last above sixteen or seventeen years. Claret is apt, in the cellar, to change to a brick colour, the consequence, it is supposed, of its mixed composition.

3535. *With respect to those wines imported in bottles*, they should not be moved from where they are first placed, except for the table. Some leave them in the cases in which they are imported; the upper side of the cases should be kept in the same position. Sillery is sometimes apt to effervesce after carriage; in that case, the bottles may be placed on their bottoms for some time, and, before drinking, the wine should be kept in ice for an hour. Brisk Champagne is also improved by being kept in ice before it is drunk, as this tends to repress the effervescence, if that is too frothy. When the glass is entirely filled with froth, on pouring out the contents of the bottle, the better qualities of the wine and the spirit evaporate. The still wines of Pierre and Sillery keep better than the sparkling kinds.

3536. *Port, as it is manufactured for Britain, requires to be kept several years in the wood, and as much more in the bottle*, in order to destroy the fiery strength of the brandy with which it is mixed; but before that time completely arrives, the vinous characteristics are sometimes gone. It then loses part of its colour and strength, becoming what is called *tawny;* but though it has become more mellow, it does not then possess the original qualities of the pure juice of the Oporto grape. Its fitness for bottling and drinking is best judged of by occasional trials. It is so hardy a wine, that even the cellars under the streets of the metropolis will little injure its quality, which is not the case with other kinds.

3537. The dry wines of the south of Europe, as Sherry, Madeira, Canary, &c., endure for a long time, and should be kept in a warm temperature. Madeira is even improved by heat and agitation, which is the reason for sending it to the East and West Indies.

3538. *The sweetest wines not only keep the longest*, but are, in fact, scarcely fit to drink till they have acquired considerable age, as they are in a perpetual state of melioration. The thinnest and briskest are those alone which may, or, rather, which ought, to be drunk when comparatively new. Sweet wines, the fermentation of which has been perfect, cannot readily become sour, because their ferment, having been expended by these processes, no more remains to excite any fermentation that may run to acid. Neither can wine that has been made dry have much tendency to acidity, for the same reason.

3539. *The establishment of the London docks* has proved a very great convenience to wine-merchants in the metropolis, who are not now, as formerly, obliged to keep wine in casks for years in their cellars. The wine now generally remains in the cask in the warehouses at the docks until it is fit for bottling. Many of the above observations, therefore, respecting the periods for which wine should be kept, are of less importance, at present, to the general than to the dock merchants, and few private individuals keep much foreign wine in casks. But we considered the above remarks as a necessary part of the history of wines, and which could not properly be omitted.

3540. *The removing of some wines to a distance* is often an affair of great difficulty, particularly the more delicate wines of France, some of which can scarcely be moved without injury. The best season for removing these, and, indeed, wines of every kind, is the spring and autumn, when the weather is mild. Cold or hot weather is prejudicial to the carriage of most wines. If transported in wood, particularly in hot seasons, they should be racked before they are removed, to prevent the lees mixing with the wine, occasioning fermentation if in bottles, they should be decanted. The most delicate bottled wines are best packed in strong cases, each bottle being wrapped in cartridge paper, and bedded in straw. In this way wine has been successfully carried to India.

Subsect. 7.—*Diseases of Wine and their Remedies.*

3541. *Among the morbid changes to which wine is liable, one of the most common is acidity;* the delicate, thin, and weak wines are most subject to this alteration; in these, on the least increase of temperature, or even on their removal, the fermentation is apt to recommence, which leads to the acetous process. This may be checked at the beginning; but after it is established, the wine is incurable. The acetous acid, when once formed, can only be got rid of by neutralizing or destroying it. For this purpose, alkalies and alkaline earths may be employed; but the alkalies, soda or potash, form soluble salts with the acetic acid or vinegar, and impart a disagreeable taste to the wine. Calcareous earth, consisting of chalk or lime, is the best substance to use, as the neutral salt which this forms with the acetic acid of the wine is insoluble in it, and forms a precipitate, which may be removed by fining. Eggs and oyster shells are the same as chalk. It was formerly the practice to employ lead, in some form or other, for counteracting acidity in wines; but we trust that this very dangerous practice has long been laid aside, the poisonous nature of this metal being now generally known.

3542. *What is technically called pricked wines* are those in which there is a slight commencement of acidity. All wines have naturally more or less of some acid, but in pricked wines it is the acetous acid which prevails. It has been shown that the principal object in the racking, fining, and sulphuring of wines is to clear the liquor from the lees, which contain a portion of the fermenting principle, and would re-excite the fermentation if suffered to mix again with it. Turbid wine may be considered as always in a precarious state, since it is constantly in danger of having the fermentation renewed, and, consequently, in running into the acetous state. It should therefore be borne in mind, that fineness is not merely a quality to please the eye, but that it is essential to the durability of the liquor.

3543. *A method of recovering pricked wines* has been recommended, and may be tried by the following experiments: Take a bottle of red port that is pricked, and add to it half an ounce of tartarized spirit of wine; shake the liquor well together, and set it by for a few days, and it will be found very remarkably altered for the better. The introduction of an alkaline salt, such as tartar imbibed by spirit of wine, has a direct power to neutralize the acidity, the spirit of wine also contributing to preserve the wine. If this operation be dexterously performed, pricked wines may be recovered by it, and remain good for some time. If a small quantity of alkali does not succeed, and the acid fermentation continues, it will be necessary to stop it by racking the wine into a cask strongly fumigated with brimstone, and then to clear it with whites of eggs, and perhaps five or six days afterward to rack and fumigate again. This will generally have the desired effect; but wine after this is not to be depended upon, and should be drunk quickly.

3544. *If wine has become too sour to be recoverable*, the best way is to dispose of it to the distillers to make spirit from, or to let the fermentation go on, and convert it into vinegar.

3545. *Ropiness*, by some called *greasiness*, is another disease to which some wines are liable. This is a change which sometimes takes place after the wine has been closely confined in casks or bottles. But it is only white wines that are subject to this disease, which consists in the appearance of a stringy matter which floats through the wine, and sometimes puts on a reticulated form. When the disease has been contracted, it may sometimes be removed by clarification with fish glue; but this remedy does not always succeed, and when it does, it diminishes a little the strength of the wine. The most efficacious remedy is racking or decanting off; and it is said that a little tannin added to the wine has the effect of precipitating the ropy matter.

3546. *Mustiness* is a peculiard isagreeable flavour, often derived from an unsound cask, or from the cork. This appears to be absolutely incurable, though it may be sometimes diminished by agitating the wine in contact with air, or by the introduction of common air or carbonic acid by pumping.

3547. *The diseases to which made wines are liable* are in every respect similar to those which are the genuine produce of the grape.

Subsect. 8.—*Choice of Wines.*

3548. *The choice of wines in laying in a stock* is a matter of considerable difficulty, particularly to the inexperienced. A habit of tasting the superior wines will alone give the palate the power of discriminating minute differences in the aroma and bouquet of the choicer kinds. But a very correct taste in wine is a rare quality; and there is sometimes a good deal of pretension in passing a judgment upon them. The particular impression on the sense of taste is also liable to be affected by the state of bodily health at the time, or by the last substance taken into the mouth. Thus, wine, after sweetmeats and fruits, frequently tastes harsh; whereas, after made dishes and cheese, wines sometimes appear better than they really are. The first object to be considered, next to the taste, from which the purchaser must judge for himself, is whether the wine is pure, and the genuine production of the country whose name it bears; and whether or not it is adulterated with any foreign substance. To distinguish this accurately, in many cases, requires great experience and a very nice practised palate. It is even said that few persons except the manufacturers themselves are judges sufficiently experienced to distinguish and appreciate the different growths of their own territory; and that even these cannot estimate properly the wines of another district. Another kind of information necessary is to be able to distinguish the condition of the wine, whether it is new, and whether it will keep or will be liable to change. Some wines may appear good that will not keep a year, and others that at first appeared but indifferent will improve so much by keeping as to be in the end excellent. Good wine is most frequently to be found among capitalists, who can afford to buy large quantities in favourable years, and who can select in their stock that which is the fittest for bottling at any particular time, not sending out any but what is fit for use, and who have a reputation to keep up.

It is scarcely necessary to add, after what we have said already in various places, that there are few articles of domestic consumption where there are more frauds practised than in wine, or where more money may be thrown away for want of good management; to say nothing of the pleasure it affords every one to place good wine before his guests, or the danger of injuring their health by offering them what is prejudicial. These considerations must serve as our apology for laying a little stress on the propriety of using some care and discrimination in procuring this article, which will be a good deal, at least, assisted by an acquaintance with the history of wine.

Sect. V.—Adulteration of Wines.

3549. Although it be acknowledged that wine is a luxury, and not a necessary of life, yet it is one of those luxuries which, used in moderation, has its use in the list of our social enjoyments. It is, therefore, exceedingly to be lamented that an article in such general request by the middle and higher ranks in this country is so frequently adulterated that to procure it genuine requires very considerable experience; and in the ordinary mode, on a small scale, this is scarcely possible without employing precautions with which few are acquainted. With respect to the danger to health arising from the use of adulterated wines, those persons who are in the habit of fraudulent practices are seldom stopped by the consideration of the mischief they do to society, and there can be little doubt that though all adulterations are not equally hurtful, many of them are of a highly deleterious nature. It is proper, therefore, that our readers should be put upon their guard against the hazard that exists of their drinking slow poison instead of a healthful beverage, to say nothing of the imposition that is submitted to when they pay for a very inferior article the price of that of the first quality.

3550. *The extent to which the sophistication of wine is carried on in Britain*, and particularly in the metropolis, would be incredible, were it not attested by good authorities; and it is an evil that appears scarcely remediable until the public is more enlightened on the subject. Wine of the best kind not being the growth of this country, few persons, comparatively, are acquainted with the true flavour and properties of genuine wine; hence frauds are more easily practised. The formation of spurious wines has become a regular and extensive trade in London; and so great is the skill with which it is carried on, that foreign wines of almost every description are imitated so as to deceive all but good judges.

3551. Lest it may be supposed that this is an erroneous or exaggerated statement, it may be proper to mention, that, so notorious and general is the practice of adulterations, that books are published containing receipts and directions for this purpose, entitled "Publicans' Guides" and "Licensed Victuallers' Directors," &c., from which much of our information is borrowed, and the sale of which sufficiently proves the use that is made of them; likewise, several prosecutions and trials have supplied evidence of these mal-practices. It is to be observed, however, that we do not vouch for the accuracy of these receipts for adulterating, or assert that they are actually the modes employed. Their publication sufficiently demonstrates that they have been more or less followed; but all the variations of them made by different adulterators will probably never be discovered.

In making these remarks, we are far from intending to say that good wine is not to be had in this country, nor that there are not many wine-merchants of high respectability who would scorn such practices as those which it is our object to expose; and it is one, and not the least of the evils of adulteration, that the fraudulent impostor does much to deprive the fair dealer of the trade and profit which are justly his due.

3552. Some of the principal adulterations of wine have been in consequence of attempts to correct the commencement of acidity. Acidity in wines is induced by a multitude of circumstances which have been already explained; and such wine is, consequently, rendered unsaleable. Merchants are accustomed to neutralize the acetic acid formed in their wines by the addition of various alkaline substances, such as the carbonates of lime, potash, and soda; but those which have undergone this species of amendment are almost always harsh and disagreeable to the taste, notwithstanding that they are freshened by a quantity of brandy.

3553. *Quicklime, from its alkaline quality*, was formerly employed in this country to correct the acidity in wine: it formed with the acid an insoluble salt, which was precipitated to the bottom of the cask. This fact explains Falstaff's accusation of his landlord, that there was "lime in his sack," intimating that his wine had begun to sour. The detection of lime, potash, or soda, used to destroy acidity, requires more chemical knowledge than is possessed by persons in general; and too imperfect acquaintance with analysis would be apt to lead into error. It will be more prudent to apply to a good practical chemist than to venture to pronounce in such case. We purposely, therefore, omit this part of the subject, as those who are already chemically informed will be at no loss

3554. *The most dangerous adulterations of wine are those where any preparation of lead has been employed.* Acetate of lead, vulgarly called sugar of lead, has been used for arresting the process of acetification. It can, however, only be used with white wines, as it precipitates the colouring matter of port and red wines. The ancients knew that it imparted a sweet taste to substances, and that it rendered harsh wine milder, but it was not universally known that it was poisonous. It appears that no other material answers the purpose so well of recovering wines beginning to be ropy; and there is no doubt but that it was formerly employed by wine-merchants for such purposes. Bishop Watson relates that its use was at one time common among the wine-merchants of Paris. In English receipt-books we likewise find directions for using it: thus, in the "Vintner's Guide, 1770," "a lump of sugar of lead of the size of a walnut, and a table-spoonful of sal enixum," are directed to be added to a "tierce (forty-two gallons) of muddy wine, *to cure it of its muddiness.*" In "Graham's Treatise on Wine-making," "to hinder wine from turning sour," it is recommended to "put a pound of melted lead into the cask, and stop it close." And, "to soften gray wine, put a little vinegar wherein litharge has been well steeped, and boil some honey to draw out the wax. Strain it through a cloth, and put a quart of it into a tierce of wine, and this will mend it."

It is probable that the deleterious nature of lead was not so generally understood formerly as at present, and that, in consequence of these directions, wine-merchants and vintners may have contaminated their wines with lead, without suspecting its poisonous nature; but now that, from the diffusion of chemical knowledge, the public is aware of the danger of this practice, and that the means of detection, having been frequently published, are easily resorted to, it is to be hoped that there are very few wine-merchants or dealers who are so iniquitous as to scatter the seeds of disease and death among those who contribute to their emolument, and to add the crime of murder to that of fraud. We believe, indeed, that lead is now rarely employed in this way, although there have been persons imprudent enough to speak lightly of the matter, and to hint that it is not so dangerous as has been supposed. It has been urged that the tartaric and malic acids form salts with lead that are nearly insoluble in the wine, and which, therefore, may be separated by fining; and that the acetate of lead, which is the only soluble salt, may be taken in small quantities without injury. Carbonate of lead, which is poisonous, is also insoluble, and falls down in wine.

Acetate of lead, which is employed in wine, it is true, is not a violent poison; on the contrary, very small quantities are employed as medicine; and it is also true that carbonate of lead is the only direct virulent salt of lead; but it has been shown that the acetate is often converted into the carbonate by the action of the stomach. On this subject Dr. A. T. Thomson observes, "These liquors, when rendered poisonous by admixture with litharge or with sugar of lead, contain the poison in the form of the citrate, which is converted into the protoxyde by being reduced by the animal juices of the stomach; and the attraction of this oxyde for carbonic acid is so great that it is rapidly converted into the carbonate; in this state it acts upon the nerves of the intestinal canal and its muscular coat, and produces disease." In some habits, particularly when the state of vitality is low, a greater quantity of carbonic acid gas is evolved in the intestines than is usual, a circumstance which favours the change just mentioned. Lead, in the small quantity and in the form in which it is used, may not be a violent and rapid poison; but every one the least acquainted with this substance must perceive the danger of admitting it into the system in any form whatever; and surely it is not expecting too much that those who perform the rites of hospitality should be careful that they do not administer to their guests slow poison. It would, therefore, be a precaution not useless, that every quantity of wine purchased should be examined for lead by a proper test for this purpose.

3555. *A ready test for detecting the existence of lead in wine* consists of water saturated with sulphuretted hydrogen gas, and acidulated with muriatic acid, and may be had of any intelligent and scientific chemist. By adding one part of it to two of wine, if lead be present, a dark-coloured or black precipitate will fall down, which does not disappear by the addition of muriatic acid. This precipitate consists of sulphuret of lead; but, to be quite certain of the metal, it is proper to examine this precipitate more particularly; for this purpose, it should be dried and fused before a blowpipe on a piece of charcoal, when it will yield a small globule of metallic lead, known by its malleability and softness.

Another method, equally efficacious, is to acidulate a little of the wine with muriatic acid, and then to pass a current of sulphuretted hydrogen gas through the liquor, when the same precipitate will appear.

Hahnemann's wine test is as follows: Mix equal parts of finely-powdered sulphur and of slacked quicklime, and expose them to a red heat for twenty minutes. To thirty-six grains of this sulphuret of lime add twenty-six grains of super-tartrate of potash (cream of tartar); put the mixture into an ounce bottle, and fill up the bottle with water that has been previously boiled and suffered to cool. The liquor, after having been repeatedly shaken, and allowed to become clear by the subsidence of the undissolved matter, may then be poured into another vial, into which about twenty drops of muriatic acid have been previously put. It is then ready for use. This test, when mingled with wine containing lead or copper, turns the wine of a dark brown or black colour.

Litharge has formerly been used in France, as well as in England, to correct the acidity in wines; but probably not at present, as it is so easily detected by the tests for lead, and better methods are known of performing the desired effect. Lead which has been detected in wine on chemical analysis has sometimes been traced to shot, used for cleaning the bottles, having been lodged in the angle at the bottom, and dissolved by the acid of the wine. We have alluded to this subject in giving directions for bottling.

3556. Besides these adulterations, various other materials will be mentioned as we proceed; but the variety of substances used by wine doctors are probably endless, and complete information upon the subject is impossible to be obtained. Nor is it possible to point out any tests by which all adulterations in wine can be detected, since many of the substances made use of are of a nature very analogous to that of the ingredients of wine itself, and cannot therefore be separated from it by any chemical agent.

3557. Having mentioned the leading facts respecting these nefarious practices, it may be well to describe in a more particular manner the adulterations of foreign wines supposed to be made by fraudulent dealers.

3558. *In the first class of wines* deception is seldom practised, from the impossibility of counterfeiting the fine flavour and bouquet so as to deceive experienced judges; thus no attempt to fabricate Lafitte or Romanée Conté would succeed. It is in the strong and the inferior wines that adulteration is most usually employed.

3559. It is said that wine is seldom adulterated by the growers on the Continent, as they are so much interested in the reputation of their produce, except, perhaps, in the worst and lowest-priced wines; but that they are so operated upon in the cellars of the exporter, and much more frequently after they arrive in this country.

3560. *That port is adulterated in a variety of ways* is a fact well known; but perhaps few persons have an idea to what extent this is practised in England. We have already mentioned, in our description of foreign wines, that the genuine wines of the Douro in Portugal are scarcely, if at all, known among us; and we have alluded to the practices of the Oporto Company, and the large addition of brandy made by them for the purpose of preparing their wines for the English market, and to render them palatable to the vitiated taste of the public. To this spirituous strength and coarseness, from the loss of true flavour, it is probable that adulterations of this wine are so easily practised. It is said that four fifths of the wine called port in the British market is of inferior quality, and therefore peculiarly subject to imitation; hence those who are not accustomed to good wine are incapable of distinguishing between what may have been imported and what is the produce of home manufacture.

3561. The frauds committed in the sale of wines called port are of different kinds. Very inferior wines are imported from various parts of Portugal, being either smuggled or paying the same duty as the wines of the Oporto Company; and are either sold here as port, at very low prices, or are used in adulterations such as will be described. Were these cheap wines offered to the public fairly as what they are, there would be no reason for complaint, as they would acquire their just character, and would be preferred by many persons on account of their price; but, by assuming the title of port, either alone or mixed, they are evidently calculated to deceive. Of this nature is the *Benecarlos* wine, a strong, coarse, red Spanish wine, and other wines of Catalonia, which are much employed in Bordeaux for making up the inferior clarets for the English market, and which may be purchased in Spain at a much lower price than port. *Figuera* is another cheap red wine, which comes from the province of Estremadura, bearing a near resemblance to inferior port. *Red Cape* is also used. It is pointed out by Mr. Redding that a return from the London Dock Company will show the immense number of pipes that are annually imported, and are cleared for the premises of the cheap port wine sellers.

3562. Various practices are used to cause new port to assume the appearance of old, and to make it pass for that of superior quality, an art known technically by the term *doctoring*. When port wine has been kept to a great age, the brandy combines so far with the wine as to lose its peculiar flavour, and permit the genuine taste of the wine to be perceived; at the same time, much of the tartar, astringent, and colouring matter is precipitated in the form of crust; the wine then has become paler, and is known by the name of *tawny* port. As this paleness of colour has been often considered as a test of age, dealers in wine have found means to imitate the wine by filtering it through charcoal, which deprives it of part of its colour; but, it should be observed, when genuine port becomes tawny through time alone, it has generally lost much of its vinosity and most valuable properties. White port is sometimes added for the same purpose.

3563. Were the adulterations of port limited to the mere admixture of genuine wines, though inferior, the case would not be so serious; but the published receipts, which let us into some of the secrets of the adulterator's trade, point out to us frauds of far greater extent.

3564. We cannot do better, perhaps, than to give a selection of those which have been already quoted in a useful book upon this subject; and though we are very far from vouching that those receipts for frauds are now acted upon, yet the very fact of their being printed and sold proves that they have been employed.

Imitation Port Wine.—"Good cider, forty-five gallons; brandy, six gallons; good port wine, eight gallons: ripe sloes, two gallons stewed well in two gallons of water; press off the liquor and add to the rest: if the colour is not strong enough, add tincture of red saunders or cudbear. In a few days this wine may be bottled: add to each bottle a tea-spoonful of the powder of catechu, mixing it well: it will very soon produce a fine crusted appearance, the bottles being packed on their sides as usual: soak the ends of the corks in a strong decoction of Brazil wood, with a little alum, which, along with the crust, gives an appearance of age."—*Vintners' and Licensed Victuallers' Guide*, p. 79.

An excellent Receipt to make neat Port.—"Let the hogshead be matched, then fill as follows: strong port, twelve gallons; rectified spirits, six gallons; cognac brandy, three gallons; fine rough cider, forty-two gallons. Cost about eighteen shillings per dozen."—*Palmer's Publicans' Director*, p. 145.

Another receipt mentioned as very general is as follows: "Benecarlo wine, two pipes; Figuera wine, two pipes; red Cape, a pipe and a half; good port, a pipe and a half; common port, one pipe; a little mountain; some brandy cowe; colouring, consisting of tartar and gum dragon." For colouring.—"Take raspings of red saunders, six ounces; spirits of wine, one quart; infuse fourteen days, and filter through paper for use. I produces a beautiful red colour for port wine."

Another.—"The juice of elderberries, one gallon; lump sugar, twelve pounds; boil together for half an hour, taking off the scum as it rises; strain through a flannel bag, and keep for use. It produces a beautiful colour for imitation wines."—*Vintners' and Licensed Victuallers' Guide*, p. 258.

We learn from one of the above-mentioned publications, the *Vintners' and Licensed Victuallers' Guide*, p. 259, what are the usual substances for performing the operation upon wines called *doctoring*. Thus bitter almonds are added to give a nutty flavour; sweet briar, orris root, clary, cherry-laurel water, and elder flowers, to form the bouquet of high-flavoured wines; alum, to render young and meager red wines bright; Brazil wood, cake of pressed elderberries and bilberries, to render pale, faint port of a rich, deep, purple colour; oak sawdust, and the husks of filberts, to give an additional astringency to unripe red wines; and a tincture of the seeds of raisins, to flavour fictitious port.

3565. It is stated, in a work intended expressly to expose these frauds, that the manufacturers of adulterated wine keep very large vats, holding from eight hundred to a thousand gallons, in which these mixtures are made; that they are more effectually blended by lying some time in such large quantities, by fretting in, on the principles already explained; and that it is from the cheapness of the articles so employed that the advertising dealers are enabled to offer port at so low a price as twenty-four shillings per dozen bottles, the bottles themselves being likewise smaller than they ought to be.

When it is apprehended that wine is about to become acid, or *pricked*, as the first degree of acetification is termed, it is a common practice to add starch sugar; if the acetification has actually begun, but advanced only a little way, then an alkali is added. Wines so treated, or doctored, with the addition of some astringent substance, are sometimes sold under some specious names, in order to account for the bad taste communicated, such as *fine old restorative port, Burgundy port, &c.*

3566. *Claret is less adulterated than port;* yet, from the prevalence of the taste here for strong wines, little even of this comes to us in the purest state. The wines of Bordeaux are generally mingled with stronger wines before they are shipped; the best with Hermitage, or Cahors, which, however, are not injurious; the second class with Benecarlos wine, which is destructive of the bouquet and aroma of the original wine; but to restore in some degree the lost qualities, the French merchants employ orris root and similar things. In England, raspberry brandy is sometimes employed in minute quantities with the same view; but the perfume then given is easily distinguished by practised connoisseurs from the natural one. This kind of adulteration, although it renders the wine less pure, is not injurious to health.

Claret, when old, becomes of a deeper colour, although port becomes lighter; hence the deep red wine of Cahors is sometimes employed to give the appearance of age. Very inferior French red wines, sold in France at a few sous a bottle, are frequently mingled with rough cider, and coloured to resemble claret with cochineal, turnsole, and similar drugs, and is then named and passed off as claret on certain occasions, without the fraud being discovered.

It is said, and with great appearance of probability, that some Frenchmen are equally ingenious with our own dealers; they prepare wines from the refuse of their vintages, or what they call wine of the "third quality," much of which, being scarcely drinkable, would find no other market than the English, being bought up at the lowest price, to be converted into *genuine* "*Vin de Bordeaux*," by means of oyster shells or lime, to destroy acidity, with brandy, colouring and flavouring materials to complete the process. Abundance of cheap *vin ordinaire* of France is now sold here as the best, or is metamorphosed into claret, and offered for sale by fraudulent wine dealers. Cheap Moselle wines are sometimes sold under the specious name of white Burgundy, &c. It is no wonder, therefore, that such wines are found to disagree with the English constitution, and that they are complained of as too cold and acid. The only remedy, as we before stated, is to purchase such wines only of the most respectable wine-merchants.

3567. *Adulteration of Sherry.*—The delicious dry wines of Spain, though naturally strong, receive an addition of brandy in the manufacture for the English market, as we have already stated; but it is said that "pale sherries" are frequently manufactured out of Cape wine, to which have been added what is called "brandy cowe," or the washings of brandy casks; some extract of almonds to give the nutty flavour; with cherry laurel water to improve the latter. Fictitious brown sherries, besides these additions, receive burned sugar and gum, benzoin, or honey.

3568. *Champagne is fabricated* in England with more boldness than any other foreign wine, few persons being acquainted with the true taste of the first quality of this wine. One species of fraud is to substitute, instead of wine of the best kind, a very inferior and weak wine made in France, but which, until lately, was wholly consumed in the district where it was fabricated, and which would not keep more than a year. This has very little alcohol, and is without the flavour or bouquet of good Champagne, but exhibits abundance of frothing and effervescence from its carbonic acid. Large quantities of this, which in France does not cost tenpence a bottle, are passed off for the best at balls, masquerades, crowded public dinners, &c., or is offered for sale at a somewhat lower price. But a still larger quantity, perhaps, sold for Champagne, is entirely fictitious, being made from gooseberries, without any of the juice of the grape, and is worth scarcely one fourth of what is paid for it. In this manner is the public plundered annually of considerable sums of money that might be usefully expended.

3569. *Madeira* may be obtained genuine, called *direct Madeira*, by applying to the merchants to whom it is consigned by the manufacturers in the island of Madeira; but the inferior wine of the north side of the island is sometimes sold for that of the south, which alone produces good wine. A wine from the Cape is also sometimes substituted for real Madeira, with some addition of flavouring ingredients. But very little actual

Madeira enters into the composition of what is sold by the cheap advertisers and placarders: their manufacture is said to consist of a cheap Vidonia, with one tenth of mountain, a fifth Cape, and a little port; this is coloured and fined.

3570. *The Cape wines*, which, when in a genuine state, are but indifferent and cheap, we might suppose would escape adulteration; but this is not the case. Those which, from their flavour, have any resemblance to other wines, are selected and sold under the deceitful names of Cape Madeira, Cape sherry, Cape port, Pontac, and even Cape Hermitage, or Burgundy, or passed off as the wines whose names have been borrowed. After that, the remainder goes by the simple name of "Cape, extremely cheap;" and a great deal is mixed with cider, and some of the adulterating materials we have already mentioned, together with the "brandy cowe," strength being the chief quality esteemed by the class of purchasers for whom it is intended, the generally bad character of this wine serving as an apology for any defect that may appear in this manufacture.

3571. It can scarcely be necessary to enlarge upon the evils produced by the extensive frauds committed in the wine trade, which we have endeavoured to expose.

3572. It must be obvious how great the loss must be to the revenue, to say nothing of the injury done to health, as well as to public morals, from the constant habit of practising imposition in all its various ramifications. Cape wine, which pays a low duty, is much employed in these sophistications, to the amount, it is said, of many hundred tons annually; but the quantity of fictitious liquor sold as wine, with scarcely a drop of grape juice, it is impossible to calculate, although no doubt it is very considerable.

3573. Formerly there were severe laws in England against the adulteration of wine. A company of vintners even took cognizance of such matters; and in 1426 the lord mayor condemned a hundred and fifty butts of adulterated wine to be thrown into the kennel. An act was passed in the reign of Charles II. even prohibiting wines from being intermingled. Of late, this subject seems not to be sufficiently attended to. To prevent altogether this base mode of swindling is probably impossible; but, by some stringent measures, it might, no doubt, be restrained. It is most important, however, that the public should understand the imposition practised upon them, for the remedy is in their own hands.

Sect. VI.—Coopering.

3574. Barrels, casks, tubs, &c., of various kinds, are articles of furniture made by the cooper; and although we have mentioned these in various places incidentally, a few words may not be useless on the subject of cooperage generally, that our readers may know how to apply to the proper person.

3575. In some places a cooper is expected to make all these articles; but in this country, in general, the workmen are brought up to confine themselves to a particular branch of the business; and we have, accordingly, *butt coopers, rundlet coopers, dry coopers, white coopers*, and *wine coopers*. Butt coopers are employed in making and repairing puncheons, hogsheads, and large casks for breweries and distilleries. Rundlet coopers confine themselves to the manufacture of small casks to hold the products of distilleries, and for other purposes, from one-gallon casks to those which contain twenty gallons. Dry coopers manufacture sugar hogsheads and casks of every kind for holding dry goods, such as clothing for the army, and all kinds of military and naval stores; as these do not require to be water-tight, they are not so well executed as the work of butt and rundlet coopers, and their price is proportionately less. White coopers make all articles of this kind in domestic use, such as small brewing vessels, washing tubs, churns, pails, &c., and they frequently add coarse turnery to their business; they use both iron and wooden hoops, the latter of ash, peeled, and white. In general, they keep shops, and expose their articles for sale.

3576. Wine coopers are employed in making and repairing every kind of wooden vessel used for holding wine, as butts, casks, &c.; but they are also the proper persons to remove and deposite wine and spirits, as they can effect this with greater safety than other persons, from being better acquainted with the strength of the vessels, and the proper way of moving them about. They are also employed in bottling and packing wines and spirits, and have often considerable knowledge of the general management of wines. Large backs and vats for breweries require often to be of vast strength to support them, and likewise the aid of the carpenter, and even the engineer. The makers of these and of coolers keep materials better fitted for the purpose than other coopers.

3577. The cooper works with few tools, and it is surprising to see the dexterity with which he handles these few. With an axe, an adze, a saw, two or three spoke staves, a large plane, and a bench made of stout plank placed upon four feet, he goes through almost all his work. The staves of the vessels manufactured by the cooper are made chiefly of oak, and are imported, cut of the proper lengths, from the Baltic or from Canada; the former, however, are the best. The edges are curved by the cooper to produce the bellying forms of casks. The heads and bottoms are of several pieces, put together by pegs called *dowells*, and are fixed in by inserting them in a groove in the staves, the projecting piece of the latter being named the *chime*. The staves themselves are held together by hoops, which vary according to the nature of the vessels; the strongest are of iron; but foreign casks are seldom bound by iron, and this metal is particularly avoided in the wine countries. In stout hoops, as those of butts, iron is the best; but when the staves are thin, the rust of iron destroys the wood. Previously to putting on the iron hoops, the staves are dried by a fire or in kilns, to cause them to shrink, that when they expand by moisture the hoops may be tight.

3578. Very great improvements have been made in this branch of business through cutting out the staves by circular saws, which perform the work with great expedition and accuracy. This was first practised by Mr. George Smart, in making the small casks called canteens, in which soldiers carry their beverage. The accuracy with which the various pieces were sawed out was such that there was no occasion to plane the edges to render them water-tight. It is worth mentioning that the casks in which butter comes from Holland are very well made; and as they may be purchased at the butter shops, when empty, at from sixpence to tenpence each, they are cheap and convenient for many domestic purposes.

CHAPTER V.

ON THE MAKING OF CIDER, PERRY, AND MEAD.

SECT. I.—CIDER.

3579. *Cider is a fermented liquor prepared from the juice of apples;* and although it is not usually reckoned among the wines, yet it belongs to that class of beverages as much as those which are made from currants, gooseberries, or other fruits.

3580. *We learn from Pliny* that both cider and perry were made by the Romans in Italy. The term cider, *cidre* in French, is derived from the Latin *sicera*, a general name for such fermented liquors as were not the produce of the grape. It was made by the Moors of Spain, from whom it was introduced into Normandy, and afterward into England. The apples and cider of Normandy are still reckoned of superior quality, and cider is prepared there abundantly, being the common beverage, as it is in Herefordshire, Devonshire, and the neighbouring counties of England, where it has acquired the highest excellence.

In Book VII., Chap. IX., "On Fruits," we gave a description of the apple: we shall here add some particulars connected with its use in making cider.

3581. *Apple-trees are propagated by seeds, or by ingrafting the scions* or shoots of such trees as are valuable for their fruit on *stocks* or trees raised from seed. *The soil* which in Herefordshire is considered the best adapted to most kinds of apples is a deep, rich loam, when under the culture of the plough; on this the trees grow wild with great luxuriance, and produce the richest fruit. Some trees, however, the golden pippin in particular, form exceptions to this general rule, and flourish most in hot, shallow soils, on a limestone or sandstone.

In the cider counties, as Herefordshire, Gloucestershire, Somersetshire, Devonshire, &c., apple-trees for cider are planted in orchards; but in some places they occasionally grow in hedge-rows, and in pastures moderately sheltered; and these might easily be multiplied in many parts of the kingdom. The fittest for such purpose are those which grow tall, so as not to overshadow the crops.

3582. *Sea air*, and situations exposed to high winds, are unfavourable to the apple. In the cider countries, where the climate is more certain than in some others, it is the custom to plant but a few good sorts, and not to mix above one or two sorts together in the making of cider.

3583. *The principal part of the cider made in England is manufactured by the growers of the fruit,* though much of what is sold in London is made by professional men, who, like brewers, devote themselves to this branch of industry, and who conduct their operations more or less on scientific principles. The varieties of apples which are cultivated for this purpose in the various fruit districts of this kingdom are extremely numerous. It is not often, however, that the maker of cider has it in his power to choose the fruit which he employs, as in most cases he is restricted to the produce of his own orchard; but as he may occasionally have an opportunity of purchasing fruit, the following particulars will be of use in directing his choice. No juice can be depended on for making good cider that does not possess, at the same time, body and flavour; the former depends on the juice contained in the pulp or flesh of the fruit, and the latter on the juice (probably an essential oil) contained in the external skin or peel, and in the seeds or pips. The apples the most agreeable to the palate are those which abound in a juice at once sweet and acidulous, whereas those which answer the best for cider have the juice both sweet and acerb, with little mixture of acid. Hence the best cider fruits, with few exceptions, are too astringent to be fit for the table.

3584. *Mr. Knight supposed* that a particular variety of apple, as well as of most other plants, has only a limited duration; and that those plants which have been propagated by grafting from one stock partake, in some degree, of the same natural duration of life in their youth, maturity, and decay, and hence he accounts for the apparent decline of some of the most valuable varieties, as the golden pippin and red streak, which were favourite old cider fruits. He conceived, therefore, that, since no variety can be preserved for an indefinite period, it is absolutely necessary to seek for new varieties by sowing the seeds, and selecting such plants so produced as possess valuable properties. Though the utility of the latter practice is acknowledged, some persons doubt, with respect to the validity of his theory, of the decline of a variety from the cause which he assigns, and rather attribute any decay which may appear to climate or other circumstances. However this may be, it is certain that some varieties of apples formerly abundant are now propagated with difficulty, and are affected with diseases formerly less frequent.

3585. *Two qualities are particularly required in the fruit proper for cider.* One is the presence of the substance called *tannin*, or *tannic acid*, without which neither cider nor perry are capable of keeping beyond the first summer. This, although indicated by the acerb flavour of the fruit, is still more correctly demonstrated by pressing the juice out of an apple or pear, and then dropping in a solution of glue or isinglass: the tannic acid combines with the gelatin, forming a precipitate, the quantity of which indicates that of the acid. The other quality is the specific gravity of the juice; if that of water be considered as 1000, that of apple juice will be found to vary from 1·050 to 1·080, and the greater the specific gravity of the juice, the greater will be the strength of the liquor which it affords.

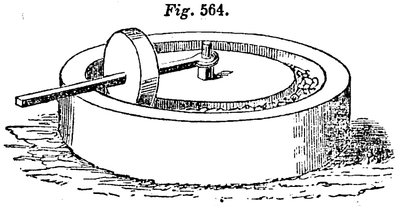
3586. *The juice of apples consists* of a considerable quantity of mucilage, saccharine matter of the same kind as that of grapes, malic acid, acetic acid, tannin, a fermenting matter, and much water. The parenchyma, or cellular membrance of the pulp, in which the above is contained, constitutes about two per cent. of the whole mass. The seeds contain a bitter principle and an essential oil.

3587. *When the fruit is gathered*, each variety should be laid apart, and formed into heaps a foot or more in thickness, in order to maturate or become mellow. It is not necessary for this purpose that they should be laid up under cover, or even protected in any degree from the weather, except during severe frosts; for apples in a loft, unless laid very thin, and carefully attended to, are apt to contract a musty taint which communicates itself to the cider. The process of mellowing has this farther advantage, besides maturing the juice, that the texture is greatly softened; and thus the operations of grinding and pressing are more easily and effectually performed. The mellowing may, in general, be known to be completed when the texture has so far given way that the thumb may without difficulty be thrust through one of the apples of an average quantity selected for the trial; it should not, however, be carried too far, as is sometimes the case. Previous to grinding, the fruits should be carefully looked over: those which are rotten are to be rejected; and those which are partially so should have the decayed part cut out.

3588. *The next operation is grinding or mashing the apples* into what is technically called *pommage:* by this the fruit is reduced as nearly as possible to a uniform consistence, in such a manner that the rinds and kernels may be scarcely discernible from the general mass, the operation proceeding slowly, with free access of air, which is supposed to promote the tendency to that decomposition which the mass is afterward to undergo.

3589. *Several methods of grinding the fruit are practised;* but that most commonly in use in Herefordshire, Devonshire, and the adjoining counties, is the bruising-stone, or apple-mill, *fig.* 564. This is a very ancient method, and is still employed in Devonshire, Herefordshire, and other western counties. The fruit is put into a circular chase, or wide groove, in a solid mass of stone, and they are crushed by a circular stone three or four feet in diameter, which is a little narrower than the groove, and which is carried round by a long axle that passes through it, and is connected at one end with an upright piece which stands in the centre of the fruit cistern. These circular bruising-stones generally weigh from one to two tons. It is essential that they should not be of limestone, nor have calcareous pebbles in their composition, as the lime would be dissolved by the acid of the apples. The best stones consist of a coarse grit, usually called "millstone grit," that is raised in the forest of Dean; but these often have the defect of being of too coarse workmanship, uneven places being left, which prevents them from bruising effectually the pips of the apples. The bruising surface ought to be worked smooth, and very hard stone, as granite, should be preferred. These circular bruising-stones are made to revolve by the hand, or by a horse, according to their weight and the quantity of work to be performed. A strong, round stick, called a *stirrer*, is employed to remove the fruit from the sides, and to keep it to the bottom of the stone.

Fig. 564.



Metal instruments should be avoided, as they are liable to be acted upon by the acid juice; and lead or copper are in particular improper.

3590. *Wooden rollers have been tried* for crushing the fruit, in the same manner as is practised with the sugar-canes in the West Indies; but it is found that the apples, being globular, and of a cellular substance, are not easily laid hold of, or, if caught, have no lengthened fibres to induce them to pass, like the cane, between plain rollers. In Ireland they use wooden cylinders, but they cover the surfaces with studs of iron, like a barrel-organ, and some use fluted rollers of wood and iron; but the acid of the fruit corrodes the iron, which, in a small degree, tinges the liquor. Upon the whole, therefore, perhaps the stone runner above described, if properly executed, is the most eligible instrument. For operations on a very small scale, where a mill is not at hand, a large block of wood hollowed out like a mortar, and a wooden pestle, might prove a succedaneum. Much depends upon the accuracy with which the grinding is performed, which ought to be continued until the pips, as well as the other parts, are completely broken down. On this account, the mill must not be choked with fruit: a moderate and rather small charge is more perfectly comminuted, and in proportionably a shorter time than a large one; the fruit should be strewed one apple in depth.

3591. *Pressing is the next operation;* and some, instead of pressing the pulp immediately after the grinding, prefer suffering it to remain in the grinding trough, or in vats for the purpose, for some time, perhaps for twelve or twenty-four hours, according to the season, that an extract from the rind and kernels may be produced. By allowing the juice to stand some time on the *marc*, the flavour of the apples is extracted, and the fermentation is sooner excited. But in warm weather there is a danger in letting it remain too long, for the acetous, and even putrefactive fermentation, are apt to set in. This danger is greater in apples collected in summer, when they are scarcely ripe, than with those which are gathered in the autumn; for in unripe apples there is abundance of natural ferment, and their juice will sometimes ferment spontaneously in a few hours, whereas the juice of apples perfectly ripe will not ferment for several days, even in a warm room.

3592. *The cider press is constructed* on the same principles as those machines which are intended to afford a strong and powerful pressure, as the packing and oil presses. The presses used in Herefordshire are a modification of the common screw press, the screw being vertical, and about six or seven inches in diameter, and the pressing boards horizontal. In Ireland, the force applied to the boards is by means simply of a lever. The hydro-mechanical press is the most powerful. The pressing is effected by putting the pulp into bags made of horse-hair cloth; some, instead of hair cloth, lay long straw under the pommage, the ends of which they turn up over it; then they cover the pommage with very fresh clean straw or reeds, upon which they spread another layer of pommage, and so on alternately, till the press is full; either method will do, but the bags are the neatest.

The first pressing should be very light, so as to extract only that portion of the juice which flows almost spontaneously; the pulp, now called the *cheese*, being then removed from the press and broken to pieces, should be exposed to the air by laying it on a coarse but clean canvass for twelve hours, turning it over from time to time with wooden forks or rakes. By this exposure the pulp will become brown, and being then pressed by a gradually increasing pressure till all the juice is extracted, will give out not only a deeper coloured, but considerably sweeter juice than that which flowed at the first pressure. In the usual careless mode of manufacturing cider, the juice, as it flows from the press, being intermixed with the finer parts of the pulp which are forced through the interstices of the hair cloth by the action of the press, is immediately transferred to the fermenting tun. This, however, is a bad practice; for the liquor will be found to ferment more moderately, and to become fine with more certainty, if deprived of this pulpy fibrous matter by running it through a common hair sieve, or through a cask with a false bottom covered with hair cloth; it may thus be obtained as clear as the wort that is produced from malt.

3593. *If the cider-maker is desirous of making different qualities of cider*, he will have ground and pressed each variety of apples separately; and, in general, it will be most profitable to make at least two kinds, a best and second, otherwise all the apples are mingled together. Some also keep apart that portion of the juice which drains without pressure, for making a superior cider.

3594. *The marc which remains after pressure*, if infused in boiling water, and allowed to remain for two days, will afford a juice that, when fermented, will make a very inferior kind of cider, formerly called *ciderkin*, and used as a common drink for labourers: at present it is called *water cider*.

3595. *The apple juice is now to be fermented.* The best vessels in which to carry on the first fermentation are casks set on end, the heads being taken out and replaced by a light moveable cover. These, being filled with juice to within four or five inches of the top, are to have their covers put on till the fermentation has commenced, which, in general, will be in from one to four days, according to the temperature and the richness of the liquor. Sometimes, in cold, unfavourable weather, the juice will remain for a fortnight or longer without fermenting; in such cases, sometimes artificial means are employed to produce it. Some persons put into the liquor a toast dipped in yeast, which is efficacious; a better method, however, is to take from two to three gallons of liquor from each cask, and to put the whole into a tub placed in a warm room; in a few hours fermentation will come on, and then the liquor is to be returned to the casks.

As soon as the fermentation has established itself, a scum begins to collect on the surface of the liquor, which should be carefully removed every morning and evening, the cover of the casks being kept on in the mean time, as it is of great importance that this stage of the fermentation should be carried through as quickly as possible. When the liquor has ceased throwing up scum, or nearly so, but while it is still giving off small bubbles of carbonic acid gas, the primary fermentation is concluded. The time which this occupies varies from twelve to thirty-six hours. The completion of the fermentation may be known by the clearness of the liquor, in consequence of the subsidence of the flocks, or muddiness, and by its having acquired a sharp vinous taste.

3596. *It is safer to rack off the cider too soon than to suffer it to remain too long.* By the latter it would certainly pass into the acetous fermentation, and a quantity of vinegar would be formed; by the former the chief defect would be want of strength, from deficiency of the alcohol. Cider, however, is not valued principally for the strength or spirit it contains, but for the agreeable mixture of this with sweetness, sourness with subacerbity; and, so that these qualities are obtained, the degree of strength is of little importance. The most desirable thing is to have sufficient carbonic acid gas to saturate the water of the apple juice, and to have the liquor sprightly, in a state intermediate between bottled cider and draught cider, as it is usually met with. Such cider, when left exposed on the table, does not become vapid, but continues to ferment slightly, and the chief objection to it in this state is want of clearness, a defect that offends the eye more than the taste. In some parts of the world it is customary to drink it in preference before the fermentation has been quite finished, and while it is still turbid.

3597. *The racking or filtering of the fermented liquor into casks is best effected* in the following manner:

For every cask of liquor take two pecks of perfectly sweet bran; scald it in two successive waters, in order to wash out all the soluble matter of the bran, and press it thoroughly; then dissolve one ounce of alum in a pail of boiling water, and pour it on the bran; let the mixture remain for six or eight hours, and then strain off the water, and press the bran as before. The bran thus prepared is to be stirred into the fermenting liquor, and the mixture is to be strained through a cask with a false bottom; the first runnings, being rather more turbid, are to be returned, but as soon as the liquor comes through moderately clear it is to be reserved. In this state it will be found agreeable to the taste, and considerably sweet; and the manufacturer may now, according to his pleasure, make of it either *sweet* or *dry cider, bottled* or *in cask.*

3598. *To produce the best sweet cider for bottling*, it is essential that the fermentation should not be complete, but that some of the saccharine matter should remain unconverted, in order that it may, by the slow fermentation (see "Fermentation" and "Brewing"), be converted into alcohol and carbonic acid gas.

3599. *After fermentation*, nothing more is required than to bottle it forthwith, and to keep it in as cool and uniform a temperature as possible for a twelvemonth or more, that it may ripen; after which it may be brought into a state fit for drinking by being placed for a week or fortnight in a warm situation. For sweet barrelled cider, the cask must be *stummed*, and then filled with the liquor; the bung must be accurately secured, and the temperature kept as cool as possible.

3600. *The term stumming signifies burning sulphur in the cask*, for the purpose of checking fermentation, it is thus performed: Take a strip of canvass cloth about twelve inches long and two broad; let it be dipped into melted brimstone; when this match is dry, let it be lighted, and suspended from the bung of a cask in which there are a few gallons of cider until it is burned out. The cask must remain stopped for an hour or more, and be then rolled to and fro, to incorporate the fumes of the match with the cider; after which it may be filled, when all fermentation will be suspended. Sometimes this process is resorted to for the purpose of giving an additional flavour to the cider. To effect this, some powdered ginger, cloves, &c., may be strewed on the match when it is made. The burning of these ingredients with the sulphur will convey somewhat of their fragrance to the whole cask of cider; but to do this advantageously, it must be performed as soon as the vinous fermentation is fully perfected. Should the fermentation return, this process must be repeated. The complete cessation of the fermentation may be known by observing whether a candle held in the bung-hole will burn. So long as there is carbonic gas escaping the candle will not burn.

For strong dry cider no stumming must be employed, but the cask, being filled to within an inch of the top, must be secured with a bung, having a hole bored through it with a round file. Into this hole, after the bung has been driven into the cask, a piece of tobacco pipe is to be inserted and secured with a little melted wax, taking care that its lower end does not dip into the liquor. A very gentle fermentation will take place, by which the sugar will be wholly converted into spirit in the course of the succeeding summer, and the cider will then be in the state of a dry wine, and will undergo no farther change as long as it is kept in perfectly close vessels.

When the cider-maker has succeeded, by successful management, in preventing the acetous fermentation, his cider will require little farther attention than filling up the vessels every two or three weeks, to supply the waste by the slow fermentation, until the beginning of the succeeding March, at which time it may be reasonably expected he will find his liquor bright, pure, and in a state for final racking, which should be done in fine weather.

3601. *The casks into which the liquor is put* whenever racked off should always have been thoroughly scalded and dried again, and each should want several gallons of being full, to expose a larger surface to the air. New casks, though they are ever so well seasoned, are apt to give a disagreeable taste to the cider: boiling them with pommage is useful. Casks that have contained spirits are best for preserving cider.

3602. *Should the above precautions be neglected*, the consequence will probably be that the acetous fermentation will take place. When, however, this has been suffered to come on, several methods have been tried to check it, sometimes with a degree of success, at other times unavailingly. One of them has been to pour in a bottle of French brandy, half a gallon of spirit extracted from the lees of cider, or a pailful of old, good cider; but this will not succeed if the cider should continue to be kept in a close, warm cellar. If removed to a cooler place, the cider may be preserved. Another remedy is the stumming described above. These remedies are innocent; but it is not safe to employ any preparation of lead, as has been done formerly.

3603. *If the cider, after being racked off into casks, remains bright*, nothing more is to be done to it; but if a scum collects on the surface, it is a proof of fermentation commencing again, and it must be immediately *racked off* into other casks to check this, which must be repeated as often as a new fermentation appears. The strength of cider is somewhat reduced by being frequently racked off.

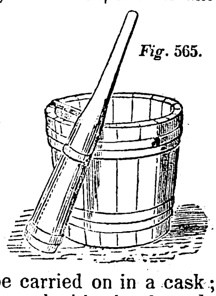
3604. *Fining will be unnecessary if the above directions are attended to;* the liquor will become spontaneously perfectly clear and bright, which will not only be a saving of farther trouble, but such liquor will keep longer unimpaired than that which has been fined. Should, however, the cider-maker, notwithstanding his care, be disappointed, he may use some of the ordinary substances for this purpose, as isinglass, whites of eggs, &c.; but all these deprive the liquor of the greatest part of its *tannin*, upon which its durability essentially depends. If fining is necessary, it may be thus performed: a pound of isinglass is soaked for ten or twelve hours in cold water, and afterward dissolved in about five gallons of cider, and well incorporated with a whisk. About a quart of this is sufficient for a hogshead of cider, and it must be stirred and mixed in the cask; but the whites of a dozen eggs, beat up along with the shells in a quart of the liquor, is thought by some to perform the operation with more certainty.

3605. *Bottling the Cider.*—Cider, in general, will be fit for bottling in about a month; but the best period is when it has arrived at the greatest perfection in the cask, which is when it is two years old; it will then soon become brisk and sparkling. As it is usually made, it will retain a considerable portion of sweetness in the cask to the end of three or four years; but then the saccharine part gradually disappears, probably by the decomposition induced by the slow fermentation. If it possess much richness, it will remain with scarcely any sensible change during twenty or thirty years, or as long as the cork duly performs its office, or resists decay. When the bottles are filled, set them by, uncorked, till the morning; let the corks be driven in very tightly: some tie them down with strong wire or twine, and secure them with melted rosin, or other material of that nature. The bottles should be laid on their sides. Both casks and bottles should be frequently looked at, and if any hissing be perceived, the bungs or corks should be removed, and replaced in a day or two, otherwise the vessels may burst. In winter they should be kept rather warm, or free from frost, and in summer in a cool place.

3606. *In making cider for the common use of the farmhouse*, few of the foregoing rules are accurately attended to. The flavour of the liquor is a secondary consideration with the farmer, whose first object is to obtain a large quantity at a small expense. The common practice is sufficiently well calculated to answer this purpose; the apples are usually gathered and ground as soon as they become moderately ripe, the pommage is pressed, and one fourth of warm water is often added to the juice, which is most frequently conveyed from the press immediately to the cellar. A violent fermentation in the casks soon commences, and continues until nearly the whole of the saccharine matter is decomposed. The casks are filled up and stopped early in the succeeding spring, and no farther attention is paid or required. The liquor thus prepared should be kept at least a year before it is drunk; it may be kept from two to five or six years in the cask, according to its strength. It is generally harsh and rough, but rarely acetous.

3607. *Cider may be made in small quantities* as well as in large, and the superabundant apples of a moderately large garden may be economically applied to this use without much trouble. The fruit should be picked free from stalks, and laid in heaps for three weeks to mellow. A tub (*fig.* 565), thicker and stronger than usual, eighteen inches in diameter, and iron-hooped, may serve for a *crushing trough*, and the apples may be made into pommage with a heavy bruiser of hard wood, not unlike that used by a street pavior.

Fig. 565.



The common clothes press, made very strong, may be employed for *pressing*, and the lower pressing-board must be placed in a tin tray to collect the juice, from which it must run down by a pipe into a vessel to receive it. The apples must be put into hair cloth, or canvass bags, to be pressed. A few must be pounded at a time, and the pressing must be done gradually, and not by using much force at once. The *fermentation* may be carried on in a cask; and a hole may be bored in the head of the cask, which can be stopped with a bottle cork, through which the juice to be fermented may be poured in; and also a cock must be placed near the bottom to draw it off by. The fermentation may be promoted by using some new yeast mixed with a little honey and flour warmed; put this into a muslin bag, insert it through the hole of the cask, and keep it suspended by a string, but do not suffer it to reach the bottom of the vessel. In warm weather the fermentation should be carried in the shade about 60°; in cold weather the cask should be placed near the fire. September is the best season for the operation. The fermentation should not be carried far, but only till the excessive sweetness of the apple is removed and has given way to a vinous taste: five or six days is generally sufficient. When the liquor ceases to ferment, or very little, it must be drawn off, and it is to be strained and received into smaller clean casks, which, when full, are to be bunged and kept for draught: after remaining for two or three weeks, the liquor may be bottled, when it will soon be ripe. Cider made in cold weather takes longer time to clear, and sometimes requires to be fined. One man pounding the fruit, and another to press and assist, will produce ten gallons of juice in a day. The juice should not be allowed to remain long in the tin tray, lest it should corrode the metal. The pounding and pressing should be as complete as possible.

In this manner, in the early part of the cider season, says Mr. Donovan, "the whole process, from the pressing out the juice to the bottling of the cider, may be completed in the space of four days; and in three other days it may be fit for drinking, of a delightful flavour, highly effervescent, and almost perfectly transparent." Those who add the ciderkin to the cider usually add brandy with a little sugar, in the proportion of a gallon of brandy to a hogshead, to supply the strength; but if pure juice only be used, this is not necessary.

3608. *Although in Herfordshire and Devonshire* they are very solicitous about the quality of the apples from which cider is made, Mr. Donovan is of opinion that this quality is of less consequence than is commonly supposed; and that good cider may be made from a mixture of all kinds of apples. Eight gallons of juice may be obtained from one hundred weight of apples, which will consist of 600 in number if the apples are large, and of six times that number when of the smallest size.

The finest cider and perry of Herefordshire is brought for exportation to the East and West Indies, and America.

3609. *If the apple juice is weak or defective in sweetness*, good cider cannot be made, and some saccharine matter should be added, as raisins, honey, or sugar, to afford more spirit, and overcome the acid. In the Lancashire Agricultural Report, by Dickson and Stevenson, p. 434, there is a receipt for making cider with honey, so as to produce a liquor of excellent quality.

3610. *The Pomona wine of Dr. Rush* is made from apples. He boiled down two barrels of cider fresh from the press into one, fermenting it afterward; if kept two or three years in a dry cellar, it affords a liquor which, according to the quality of the apple from which the cider is made, has the taste of Malaga or Rhenish wine. It is a pleasant drink in summer mixed with water.

3611. *The quantity of alcohol in cider* is inconsiderable; and when extracted by distillation is of a bad quality, except it be repeatedly rectified. In Normandy they make a great deal of what is called *eau-de-vie* from their cider; but it is very inferior to brandy from wine, though often employed to adulterate the latter.

3612. *Cider is not so nutritious as malt liquor;* but it forms an excellent beverage for labouring men in the summer months, its acid assisting materially in quenching thirst. Rough Herefordshire cider has been recommended as an antiseptic in cases of low contagious fever instead of port wine, when the latter cannot be procured.

Sect. II.—Perry.

3613. This beverage is made from the fruit of the pear-tree, which is of the orchard kind. There are many varieties; but for the purpose of perry the Tinton squash pear is in the highest esteem in Gloucestershire. It is an early fruit, remarkable for the tenderness of its flesh. The liquor made from this fruit is pale, sweet, yet remarkably fine, and of a strong body. The Oldfield pear is a favourite, remarkable for the fine flavour of its liquor. The Barland pear of Worcestershire is in great repute, as is also the red pear. Besides these, there are many others of great merit among those of Herefordshire and the adjacent counties.

3614. *The pear is more properly a naturalized than an indigenous fruit* in this country; it is more hardy than the apple, and may be cultivated in almost every part of England with nearly as much success as in Herefordshire. Like the apple, it grows with the greatest luxuriance in strong deep soils, and in these the finest liquors are at present obtained; but inferior kinds will flourish in almost any soil that is not incommoded with water, even such as will scarcely produce herbage. The pear is an extremely long-lived tree, and the same variety may in consequence be very long kept in cultivation.

3615. *Every variety of this fruit which possesses colour and richness is capable of making perry;* but a good perry pear requires an assemblage of qualities which will be rarely found in the same fruit. It must contain a large proportion of sugar, or its juice can never possess sufficient strength; and unless it be at the same time astringent, the liquor produced from it will be acetous whenever it ceases to be saccharine; in the latter state it will agree with few constitutions; in the former with none. The juice of the best perry pears, according to Mr. Knight, "is so harsh and rough as to occasion a long-continued heat and irritation in the throat when the fruit is attempted to be eaten; yet by being simply pressed from the pulp, it becomes rich and sweet, without more roughness than is agreeable to almost every palate." This circumstance, though extraordinary, does not stand alone in the vegetable world; there are many cases where similar changes take place with acrid vegetable substances.

3616. *The pear requires a certain state of maturity* to afford perry in the greatest perfection; it should be ripe without being mellow or decaying; when it has not obtained the proper degree of ripeness, an excess of fermentation cannot be prevented; and when it has exceeded it, the liquor rarely ferments kindly, and is extremely apt to become sour, probably by having lost too great a proportion of its astringency; hence few kinds are found to improve by being kept after they have fallen from the trees. The produce of the same pear-tree ripens very irregularly; the planter must therefore have a considerable number of trees of each kind he plants, or he will rarely have a sufficient quantity ready to be ground at the same time. Even when the fruit has fallen spontaneously from the trees, a fourth at least of some kinds will be found immature or decaying, and totally unfit for making fine perry; this should be (though it rarely or never is) separated from the rest. Mr. Knight attributes to this neglect a certain crude and harsh acid which dwells upon the palate, and which perry is seldom free from; and to the same cause it may be owing that perry, even when genuine, does not agree with so many constitutions as cider.

The pear, however, though generally producing a liquor inferior to cider, has many advantages over the apple; it is capable of succeeding in a greater variety of soil, and is more productive of fruit.

3617. *The best pears for perry*, or, at least, the sorts which have hitherto been deemed the fittest for making this liquor, are so excessively tart and harsh, that no one can think of eating them as fruit; for even hungry swine will not feed upon them. In Worcester, Gloucestershire, and the adjacent counties, they are planted in the hedge rows and the most common fields; a practice which, perhaps, should be more followed, as pears are capable of affording a light and agreeable nourishment, either in soups or stewed when green.

3618. *Mr. Knight states that in the making of perry the pears are ground and pressed* in exactly the same manner as those of apples in the manufacturing of cider, but that it is not usual for the reduced pulp to be suffered to remain any length of time without being pressed. It has never been the practice in Herefordshire, or in the counties in the vicinity of it, to blend the juices of the different varieties of the pear, in order to correct the defects of one kind by the opposite properties of the other. It is, however, he allows, more easy to find the required portion of sugar and of astringency, as well as of flavour, in three or four varieties than in one; hence, he supposes, a judicious mixture of fruits affords a prospect of great benefit.

3619. *The juices of the pear* and the apple are constituted of the same component parts, but the proportions are different. In the juice of the pear the *tanning principle* is predominant, with a less proportion of sugar, mucilage, and colouring matter.

3620. *The method of fermenting perry* is nearly the same as that of cider; but the former does not afford the same indications as the latter by which the proper period of racking off may be known. The thick scum that collects on the surface of cider rarely appears in the juice of the pear, and during the time of the suspension of its fermentation the excessive brightness of the former liquor is seldom seen in the latter; but where the fruit has been regularly ripe, its produce will generally become moderately clear and quiet in a few days after it is made, and it should then be drawn off from its grosser lees. An excess of fermentation is prevented by the means used in the making of cider, and the liquor is rendered bright, if necessary, by isinglass.

3621. *In the after-management of perry*, the method is the same as that of cider; but it does not so well bear situations where it is much exposed to change of temperature. In the bottle it almost always retains its good qualities, and in that situation it is always advisable to put it, if it remains sound and perfect at the conclusion of the first succeeding summer.

3622. *On the whole, the pear-tree furnishes a less popular liquor than the apple*, but is more productive, furnishing in the proportion of 600 gallons of liquor to the acre, when the trees are full grown and in good bearing: the produce of a single tree will often be twenty gallons of perry. It is to be observed that, though perry is made in a much smaller quantity than cider, yet the former, of the best kind, and bottled, is generally esteemed as quite equal to the latter.

3623. *Mr. Booth, in his work on wine-making*, thus describes a sort of wine in which pears were employed: "In the north of France, having heated fifty-five pounds of the juice of wild pears to 180°, I added about a tenth of that weight of raisins, and bunged up the whole in a cask. In a short time the heat of the liquor had fallen to 77°, when I drained out the raisins, bruised them, returned them into the must, and closed the cask, so as to allow the fermentation to take place. A fortnight after, the wine or perry was racked into stone cans, and, after standing three months in the cellar, it was reckoned by good judges equal to the best wine from grapes."

Sect. III.—Mead.

3624. *Mead is a vinous liquor prepared from honey* diluted with water and fermented, and which was formerly much used in England, as well as among many northern nations. It appears to have been a beverage of great antiquity, being, perhaps, the only fermented liquor made in the northern parts of Europe to which the cultivation of corn had not yet extended, and where the climate was too cold for the vine; it therefore rivalled the wines of the south. It is the Hydromel of the Romans; Pliny records, and Virgil celebrates, the drinks made with honey mixed with fruits. By the Saxons it was called *Meda*, whence the *mead* and *metheglin* of modern times. It was drunk in great excess at the festivals among the Norsemen, and filled the scull-cups in the hall of Odin. It is said that Attila, king of the Huns, died from indulging too freely in this favourite liquor.

Mead vas well known to the ancient Britons, and was highly valued by their posterity long after they were acquainted with other liquors. The mead-maker held a considerable rank in the courts of British princes. Honey appears to have been more abundant formerly than at present, when the extension of agriculture has deprived the bees of much of their favourite wild food. The introduction of sugar has likewise, to a considerable degree, driven honey out of the field, and the production of corn has given rise to the manufacture of ale. Of late, mead has been little used in England, and is now scarcely known.

Though mead and metheglin appear to have been the same, yet some have drawn a distinction, considering the latter to be the superior beverage. It is said that Queen Elizabeth was so fond of metheglin, that she had some made for her special drinking every year.

3625. *The composition of honey* will be stated in our account of that substance, Book X., Chap. XIV. Diluted with water, it is susceptible of the vinous fermentation without the addition of yeast: but mead, when made from honey and water only, is flavourless and heavy; it is much improved by the addition of fruit-juice and spices.

3626. *The method of making mead without fruit, as commonly practised in England,* is as follows: Boil honey in water for an hour, in the proportion of three to four pounds of honey to a gallon of water. Skim it carefully, draining the skimmings through a hair sieve, and returning what runs through. When of the proper coolness, stir in yeast, a tea-cupful for nine gallons, and let it ferment. Some add half an ounce of hops to preserve it; but this is not usual. Tun or transfer it to the cask, and ferment it in the usual manner. Put it in a cool cellar, and in a year it will be fit to bottle. Strong mead, if well made, will keep many years, and, indeed, requires to be kept one or two before it is sufficiently meliorated; it improves by time. Some put two lemon peels to each gallon while it is fermenting; others add cinnamon, ginger, cloves, mace, and rosemary. It was formerly a custom to add some ale wort, and it was then called *Welsh braggart.* Mead may be made into a very agreeable beverage, not inferior to many foreign wines.

3627. *Macquer, in his "Dictionary of Chemistry," directs* to choose the whitest, purest, and best-tasted honey, and to put it into a kettle with more than its weight of water; a part of this liquor must be evaporated by boiling, and the liquor scummed till its consistence is such that a fresh egg shall be supported on its surface without sinking more than half its thickness; then the liquor is to be strained and poured into a barrel, which, when nearly full, must be kept in a warm place, taking care that the bung-hole be slightly covered, but not closed. The fermentation which ensues will subsist during two or three months, according to the degree of heat. During the fermentation the barrel must be filled up occasionally with more of the same kind of liquor of honey (some of which ought to be kept apart), to supply what works out of the barrel. When the fermentation ceases, and the liquor has become vinous, the barrel is to be put into a cellar and bunged up. In about a year the mead will be fit to be bottled.

3628. *Mead is still a favourite beverage among the northern nations,* and is still drunk in large quantity in some parts of Europe, particularly in Russia, Poland, and Lithuania, where a vast deal of honey is produced in the forests.

"*The process of brewing mead in Poland* is very simple; the proportions of the ingredients are three parts of water to one of honey, and 50 lbs. of mild hops are used to 163 gallons. When the water is boiling, and it is kept stirring till it is milk-warm, it is then put into a large cask, and allowed to ferment for a few days; it is then drawn off into another cask, wherein there has been aqua vitæ or whiskey, bunged quite close, and afterward taken to the cellars, which in this country are excellent and cool. This mead becomes good in three years' time; and, by keeping, it improves, like many sorts of wine. The mead for immediate drink is made from malt, hops, and honey, in the same proportion, and it undergoes a similar process. In Hungary, it is usual to put ginger in the mead. There are also various other sorts of mead in Poland, made of honey, wild cherries, berries of the Cornus mascula, and raspberries; they all undergo the same process, and are excellent after a few years' keeping."—*Loudon's Encyclopædia of Agriculture.*

3629. *Mead is made in Russia in great perfection.* It is there, according to Mr. Tooke, of two kinds, white and red. To make the first, two poods of white honey are mixed in five ankers of clear river or soft water, and boiled and skimmed till nearly an anker is boiled away. The liquor is then strained through a fine sieve or piece of linen into a broad, open vessel, and mixed with a couple of spoonfuls of beer lees and a pound of white bread, *kalatsch.* After it has stood in this vessel in a moderately warm place, and fermented for thirty-six hours, it is poured through another sieve or piece of linen into a cask, in which has been previously put a pound of small-shred isinglass for clarifying it. For red mead, to one pood of honey they add eight vedross of water, and reduce them by boiling to six vedross. When cold, the juice of about half a chetverick of pressed or bruised cranberries, strained through a sieve, is mixed with it. A small complement of yeast is then added, and some isinglass or whites of eggs are thrown in to fine the liquor. Cinnamon, cloves, ginger, mace, and other spices are infused. It is then placed in a cool cellar, and, after standing there for some weeks, it is either bottled for use, or drawn from the cask direct. Strawberries, raspberries, and cherries are sometimes mixed with the mead to improve its flavour. Honey is so abundant in some of the forests of Russia as to form a considerable article of trade, and some tribes scarcely follow any other employment than the rearing of bees. Some individuals possess thousands of hives of wild bees, which are formed in the trees.

3630. *Mead is made with a mixture of fruit juice* in a variety of ways. Together with honey, white and red currants and raspberries are employed; likewise, the rinds of oranges and lemons are added. Aromatics and spices are used occasionally; as the leaves of rosemary, lavender, and sweet briar, and cinnamon, cloves, and nutmeg. These additions are made towards the end of the fermentation, and are suspended in the cask, before it is bunged, in a muslin bag, which may have a piece of flint in it to weigh it down. The mead should be kept in the wood from six to twelve months, and from nine months to two years in the bottle.

3631. *White Currant Mead.*—Infuse two gallons of white currants bruised, thirty pounds of honey, and three ounces of tartar, in fifteen gallons and a half of boiling water. Stir this together for a quarter of an hour, and then set it to ferment. When the fermentation is complete, and the liquor clear, add one gallon of brandy, and bottle it immediately. A slow fermentation will go on in the bottle, and in a few months it will be brisk and fit to drink. If it requires to be still, the fermentation must be continued longer, according to the principles already laid down.

3632. *Red Currant Mead.*—Instead of the above-mentioned quantity of white currants, use six quarts of red currants and two of black, with twenty-five pounds of honey and a pound of red beet root cut into thin slices Proceed as before.

CHAPTER VI.

ON THE MAKING OF VINEGAR.

3633. *Although most of the vinegar used in domestic economy is purchased*, there are yet many occasions where it is useful to make it, in order to secure it of good quality; and sometimes liquors become sour, and cannot be made any use of except by converting them into vinegar. It is important, also, that the nature of a material so much employed in many culinary operations, and as an article of nutriment, should be well understood.

3634. *Vinegar was known for many ages before any other acid.* It is mentioned by Moses, and, indeed, seems to have been common among the Israelites, and other Eastern nations at a very early period. It was at first made from wine, and the formation of wine vinegar is probably as ancient as the liquid itself from which it was produced; although the improvement of the process has been the result of the observations of ages. Vinegar was much in use among the Greeks and Romans, who employed it both in their cookery, as a luxury, and as medicine. It was found highly useful in their armies, the soldiers being always obliged to carry some, for the purpose of mixing a little with water, to obtain a grateful drink, both cooling and excellent to quench thirst. This practice is still followed in some of the warmer parts of Europe, particularly among the Spanish peasantry, who are accustomed to mix about a gill of wine vinegar with a gallon of water, and a tea-spoonful of salt, for a common beverage; and with this drink alone, and bread, they frequently sustain the labours of the field, exposed to the heat of the sun in their warm climate, and are as healthy and athletic a race as any in Europe. They may occasionally, when their work is over, indulge in a glass of their *vin de pays*, or even of some kind of spirits, but during their labour they find vinegar and water sufficient. The uses to which vinegar is applied among us are too numerous and well known to be here enumerated. As a condiment, vinegar is grateful, and, used moderately, is wholesome. It appears, in general, to be a useful addition to fatty and gelatinous substances, rendering them more digestible; but if taken in too large quantities, it is highly injurious to the stomach.

3635. *The name is derived* from the French *vinaigre*, or *vin*, wine, and *aigre*, sour. Strictly, therefore, the term vinegar should be confined to what is made from wine; and that made from ale is sometimes called *alegar;* but as the acid is the same, however it may have been procured, the custom is now to call all the varieties of it by the name vinegar.

SECT. I.—GENERAL PRINCIPLES OF PRODUCING VINEGAR.

3636. In Book VIII., Chap. II., when treating of fermentation, we stated that every liquor that has completely undergone the vinous or spirituous fermentation is spontaneously disposed to pass into the acetous stage, and will do so except means are taken to prevent it. Thus, if wine, ale, beer, or any other containing spirit and mucilage, be exposed for some time to air not too cold, that is to say, from about 75° to 80°, or a temperature somewhat higher than our ordinary summer heat, they will undergo a second fermentation, and become sour; and the sourness will increase so much after some weeks or months, that they will be found converted into a weak vinegar. But if this natural process is left to itself, the change might be too gradual or slow to obtain vinegar in perfection, as the first acetified portion will become mouldy and go on to the putrefactive state before the last has become sour. It is necessary, therefore, to add either yeast or an acetous ferment to hasten the new fermentation; this new fermentation must also be stopped in time, or as soon as it has arrived at the completely acetous state, and the acid has attained the highest degree of perfection and strength, otherwise the liquor would speedily be deteriorated; the acid taste would gradually lessen, and at last disappear altogether, being succeeded by an offensive smell proceeding from the putrefactive fermentation; a mouldy watery liquor remaining, with scarcely any acidity. It therefore requires skill and experience in the vinegar-maker, not only to employ the best process for producing the acid liquor, but to determine when the vinegar is in a fit state to be drawn off and closely barrelled. Thus, as we have stated of fermentation generally, the formation of vinegar is the result of natural laws, and we can only regulate the circumstances under which they act.

SECT. II.—OF THE DIFFERENT SORTS OF VINEGAR.

3637. *The sorts of vinegar in common use may be divided into*, 1, wine vinegar; 2, raisin vinegar; 3, malt vinegar; 4, sugar vinegar; 5, fruit vinegar; 6, wood vinegar, or pyroligneous acid. All these consist of the same acid, the acetic diluted with water; containing, likewise, several impurities, as gluten, mucilage, and sometimes other vegetable acids, according to the materials from which the vinegar is made. The formation of all these, with the exception of wood vinegar, depends upon the same general principles, although, in consequence of the varied nature of the ingredients from which they are produced, the processes necessarily differ. The best vinegar is made from white wine, but ordinary vinegar is produced from malt.

Subsect. 1.—*Wine Vinegar.*

3638. We commence with the method of preparing *wine vinegar* on the Continent, not because this can be practised in English domestic economy, but because it is the most ancient, and the best mode, and likewise because our processes have been derived from it. Wine vinegar is properly the vinegar of genuine foreign wine, methodically prepared, as in Germany, France, and Italy, and does not include those which are made from cider, malt wines, or made wines of any description whatever. All wines, especially those of a weak kind, either spontaneously, or by repeated fermentations, may be converted into a kind of vinegar. Observation of the frequent and spontaneous acidity in wines no doubt gave rise to the preparation of the more permanent and pungent liquid which is obtained by a regular process, such as the following:

3639. *Method of making Wine Vinegar in France.*—Large vats, in pairs, open at top, but fitted with close, moveable covers, are placed in a row under a shed open at the south side, so as to be heated by the sunbeams by day, and exposed to the air at night. Between each pair, a capacious and strong open receiver, made of oak and well hooped, is sunk in the earth, so that the cock in each cask near the bottom may command it. In this receiver a pump is placed, and near it a stage and a ladder for a man to ascend and work the pump, and put the covers on and off the vats; a few feet from the bottom of each cask a strong, perforated false bottom is fixed, on which the substance, technically *rape*, or ferment, is placed. The rape consists of the foot-stalks of the bunches or clusters of grapes, or of the marc that has been preserved in the manner we shall afterward describe. The use of the rape is, to sour the wine, and it is disposed thus: first, a layer of vine twigs is laid, some inches thick, on the perforated or grated bottom, to prevent the rape clogging up the holes or falling through. Then the vats are filled up with wine to within about six inches of the top. This is poured over the rape until one vat is filled, and the other half full. In two or three days, according to the temperature of the atmosphere, the wine in the half-filled vat begins to heat and ferment, and the heat will increase for several days successively, without any appearance of the like during that time in the vessel that is full. The cock of the full vessel is then turned, and the wine, as it flows into the receiver, is pumped over the fermenting rape to check the fermentation, which otherwise would proceed too rapidly, and the heat excited would cause the spirituous part of the wine to dissipate and leave the liquor vapid. In two or three days, or less time, the rape in the other vessel begins to heat and ferment, when recourse must be had to the same means of checking the fermentation by pumping up the wine of the full vat from the receiver as before. This must be alternately done every day, and in very warm weather once in every twelve hours. In winter it generally takes from twenty-four to thirty-six hours to heat and ferment; both vats successively augment in heat and vigour of fermentation until the vinegar is perfected or finally made, which is usually in about fourteen or fifteen days in summer. In winter it proceeds more slowly, and that in proportion to the coldness of the weather.

During the fermentation the full vessel must be kept always open at the top; but the half-full vat should be kept accurately covered, to prevent the dissipation of the spirit of the wine by the heat, and also the loss of the carbonic acid gas that is disengaged, and to cause it to react upon the liquor fermented by being entangled in the fluid; if both vessels are kept open, the liquor may be soured, but it will be converted into a flat, instead of a sharp, pungent, strong vinegar. At the time when they pump the wine out of the full vessel, a scum rises that should be taken off; and in the half-full vessel there ought to be left a hole, stopped up with a plug, occasionally to give vent, and examine the progress of the operation, which also keeps in the volatile acescent vapour generated by the fermentation; the latter is known to be completed when the hissing noise in the half-full vessel ceases.

3640. It will improve the vinegar, after it is made, to let it stand some time on the rape. If the weather or climate is warm, wine vinegar may be made in the summer season in the open air; if cold, artificial heat within doors will be necessary.

Since, in casks that have never been used for this purpose, vinegar is made more slowly and with greater difficulty than in those which have previously served this purpose, the latter are preferred, and are called in France *mères de vinaigre*, mothers of vinegar.

3641. *In the acetous as well as in the vinous fermentation, an intestine motion,* a swelling, a hissing noise, and an ebullition, may be perceived; but the heat produced by the latter is scarcely sensible, whereas that produced by the former is very considerable. The vapour, also, which comes from vinegar is not so vinous as that of fermenting wine.

3642. *Vinegar does not deposite tartar* as wine does, even though it has been made with wine that has not deposited its tartar, which proves that this substance is decomposed in the process.

3643. *Wine is also converted into vinegar* without the additions mentioned above, simply by adding wine, especially when on the fret, to vinegar already made, and exposing it to a proper heat. The casks are always kept nearly full, by taking out of them at intervals about a third or a fourth part, replenishing them with wine, and again bringing the contents to the state of vinegar. In this manner the best white wine vinegar of Orleans is made.

In France vinegar is usually made from poor wines, or from such as have become too sour. Wine vinegar is considered purer than any other kind, and it is generally stronger than the usual malt vinegars of this country. They have there both white and red vinegar made from white and red wines. Red vinegar may be deprived of its colour by making it pass through animal charcoal, produced by calcining bones out of contact of the air till they are black; the product is not, however, pure animal charcoal, but it contains a large quantity of this substance, together with a little phosphate and carbonate of lime; it is therefore necessary afterward to digest the burned bones in diluted muriatic acid, to remove their earthy salts, which otherwise would be taken up by the vinegar. Red vinegar may likewise be rendered white by mixing it with milk and agitating the mixture; the colouring matter of the wine will combine with part of the milk, and will fall down as a sediment.

SUBSECT. 2.—*Raisin Vinegar.*

3644. *A superior kind of vinegar, sometimes used in pickling, is occasionally prepared in this country from raisins,* and the manner of making it is evidently an imitation of the processes used on the Continent for producing wine vinegars. The cheapest kind of raisins are employed, and an equal quantity of coarse sugar is added to increase the quantity of the fermentable matter, as, in this case, the process of vinous fermentation is to begin.

To every hundred pounds of raisins, and as many of sugar, a hundred gallons of water are added, of the temperature of 65° or 70°. The mixture being well stirred, spontaneous fermentation commences in a few hours, the raisins containing a natural ferment. The fermentation continues three or four days, the temperature rising to about 80°; when this has proceeded as far as it is judged necessary for the production of spirit, it is checked by racking off the liquor, which is put into casks having false bottoms pierced with holes, into which had been previously put the rape, consisting of the residuum of husks, stalks, &c., of raisins from a former process of the same kind, and which have been soured, in order to cause the acetous fermentation to begin. The casks are placed in a line, and each is filled entirely, and only half, alternately, with the wash, which is a kind of raisin wine that has been brewed. Were the liquor to remain so, it would soon heat and ferment too rapidly, so as to pass into the putrefactive stage; therefore the fermentation must be checked in the full cask by drawing some of the liquor out into that which is half full. Next day the process is reversed by putting back the liquor that was taken out, and leaving the casks, now full, to be again half empty; and so on each day, or oftener, if necessary, in order to check the fermentation, precisely as in the French method, which we have described, until the acetification is complete. The casks are placed in an apartment heated to about 80° by means of a tube that opens into the external air, passes through a furnace, and thus delivers the air within it in a heated state into the apartment. The admission of heated air demands the exit of an equal quantity from the apartment; and thus a constant circulation of air is kept up, which occasions a ventilation very useful in stopping the progress of putrefaction. When the vinegar is formed, it is clarified by means of isinglass, and put into well-closed casks.

It is to be observed that genuine wine vinegar or raisin vinegar differs from that formed either from sugar, beer, apples, &c., in containing tartar, by which peculiarity it may be distinguished, except where tartar has been added to other vinegar for the purpose of disguising it.

SUBSECT. 3.—*Common Vinegar.*

3645. *Common vinegar is most usually prepared in this country from malt.* From what we have already said here, and on the subject of brewing, it must be obvious that all that is necessary for the formation of vinegar is to ferment the wort from malt, and to suffer the vinous fermentation to pass on to the acetous stage, instead of checking it as in the brewing of beer.

3646. *Malt vinegar is prepared in manufactories.* The first operations are nearly the same with those of the brewer. A mash of ground malt and hot water is made, and, after infusion for an hour and a half, it is conveyed into a cooler a few inches deep, and thence, when sufficiently cooled, is transferred to the fermenting tun, where it is mixed with yeast, and kept in fermentation for four or five days. The liquor (which is a strong ale without hops) is then distributed into smaller barrels, set close together in a chamber, in which a moderate heat is maintained for about six weeks by a flue that goes all round, or by hot air, or by the sun, during which time the fermentation goes on equally and uniformly, and passes from the vinous to the acetous fermentation. The sour liquor is then emptied into barrels, which, in the summer, are set in rows in a field in the open air, the bung-hole being only covered with a loose tile, that the air may have free admission; in the winter they are kept in a room with a *stove*, to increase the acetification. It would require a very long time to complete this process if no ferment was used; but for this purpose they sometimes introduce into the barrels, upon a false bottom pierced with holes, a quantity of the refuse of raisins, or other fruit, left by the makers of raisin and other made wines. This, called *rape*, acts as an acetous ferment, and abridges the time that otherwise would be necessary, and prevents failure, to which the process would be liable. By this means the operation is finished in four or five months. These *rape tuns* are worked by pairs, in the same manner as was described in making vinegar from wine. One of the pairs is quite filled with the vinegar from the barrels, and the other only three quarters full, so that the fermentation is excited more easily in the latter than in the former, and every day a portion of the vinegar is laded from the one to the other, till the whole is completely finished.

As soon as the vinegar has acquired its greatest degree of sourness, the process is stopped; otherwise, by a continuance of the fermentation, the next stage, the putrefactive, would commence, and then the acidity will diminish, and ultimately disappear. For this purpose, as soon as the vinegar has acquired the requisite degree of strength, as indicated by its taste, it is racked off its lees into other casks, in the same manner as in the case of ale or wine.

The vinegar in this state, however, though sufficiently strong, is yet thick and foul, and requires to be *clarified* before it is fit for use or for keeping. To render it clear and transparent, isinglass is dissolved in a small quantity of the vinegar, and the solution is put to that in the casks. After this the feculencies will subside, and, as soon as it is quite clear, it is again racked off, and is fit for sale. The usual calculation is that one barrel of malt will make thirty gallons of good house vinegar.

From the above account, it is evident that common vinegar is very impure and very dilute acetic acid, containing, besides the acid and water, a large quantity of mucilage, some colouring matter, a little spirit, and a little sulphuric acid added by the manufacturer, which is permitted by the excise. Its agreeable odour and taste are well known, and its colour varies from straw-yellow to deep brownish red.

3647. *The colour of vinegar* varies according to the materials from which it has been obtained; what is manufactured in England is usually artificially coloured by burned sugar.

3648. *Alegar* is made by fermenting strong ale upon the cuttings of the vine, unripe grapes, or cheap raisins, and proceeding as in common vinegar.

Subsect. 4.—*Vinegar from various Substances.*

3649. *As vinegar may be made from all substances capable of being fermented,* or which contain saccharine matter, the sources from which vinegar may be obtained are numerous. For this purpose, in domestic economy, various materials are occasionally employed, as sugar, either white or brown, raisins and sugar, currants, gooseberries, apples, or other fruit; and, if attention be given to the right principles, the process of making vinegar from all of these is by no means difficult.

3650. *To make Sugar Vinegar.*—Take four pounds of the cheapest loaf sugar, and add to it three gallons of boiling water in a tub; this is about the proportion that would make a strong wine. When the solution has cooled to blood heat, ferment it with two or three table-spoonfuls of yeast, in the same manner as beer is fermented. Continue the fermentation for a few days, until the vinous fermentation is completely at an end, which is known by the sweetness having disappeared. The yeast must then be skimmed off, and the liquor poured into a small cask, leaving the dregs at the bottom. The cask should not be above three parts full, and it should be set either in the sun or near the kitchen fire, with its bung-hole only covered with a loose tile or slate. The temperature in which it is kept should be as uniform as possible, about 80°; after a few weeks the liquor will be found sour; this sourness will increase, and in about eight months will be sufficient. A quantity of sediment will be deposited in the cask, and the vinegar must be drawn off by a gimlet hole, made a little way above the bottom. If it is not transparent, it may be fined by isinglass, after which it may be bottled: the bottles should be kept in a cool place. If, after some months, the vinegar appears turbid, it should be decanted, strained, and bottled again; and it may be necessary to repeat this more than once, for all common vinegar, home-made or purchased, is liable to this change.

3651. *Another method,* which is considered by some as superior, is the following: Dissolve sugar in hot water in the proportion of eighteen ounces of sugar to every gallon of hot water; when the solution has cooled down to 75°, add a sufficient quantity of yeast to cause it to ferment. In two or three days the fermentation will have pretty well advanced; then pour off the clear wash from the lees into a cask, and add an ounce of crude tartar, and one of bruised raisins, for every gallon of water. Expose the whole to the acetifying process for the usual time, as in the last method; then rack off the vinegar and fine it; bottle it.

3652. *Fruit vinegar* is made by fermenting the juice of various fruits; but as they must possess saccharine matter sufficient to bring on the vinous fermentation, some fruits which have too little sugar, as currants and gooseberries, must have some added to their juice. Some persons, from economy, make vinegar from the pulp and husks of grapes, gooseberries, raisins, or other fruits, after wine has been made from the juice. Add half its weight of coarse sugar to the pulp; when it begins to ferment, add a gallon of boiling water for every two pounds; stir it well, and let it steep for two days; then strain it; when cool, ferment it with yeast for a week or ten days, and then put it into a barrel, with a pint of vinegar and two ounces of loaf-sugar for every gallon. Lay a loose tile over the bung of the cask; set it in a warm place, and in three months it will be complete; then bung it.

3653. *Treacle vinegar* may be made in a similar manner.

3654. *Cider vinegar* is made by fermenting the juice of good apples, which require no sugar; or it is made from cider which has become too sour to drink, or any poor cider. A cask that has been previously used for holding vinegar is best to make it in. Some mix cider and honey for making vinegar.

3655. *Any sort of wine,* whether foreign or domestic, that has not turned out well, may be easily converted into vinegar, by infusing it in pounded gooseberries, currants, raisins, or the *marc* remaining after making home made wine of any kind; then straining it off, and exposing it to the air in the proper temperature.

3656. *Gooseberry Vinegar.*—Take gooseberries when full ripe; mash them in a tub or marble mortar, and to every quart of the mashed fruit add three quarts of water; stir this well, let it stand twenty-four hours, and strain it through a coarse bag. To every gallon of the strained liquor add four pounds of brown sugar, or four pounds and a half of honey; the latter is preferable. Put the mixture into a barrel, which it should fill about three fourths, and add to eight or nine gallons of it one pint of good ale yeast; cover the bung-hole of the cask with a slate, to exclude the dust, and place the barrel in the sun in summer, or a litttle away from the fire in winter. The mixture will soon begin to ferment. Continue the fermentation, by keeping the liquor at the same temperature, till the taste and odour indicate that the vinegar is complete. When the liquor has become perfectly clear, draw it off into bottles. It will keep much better if it be heated nearly to the boiling point, which is best accomplished by putting the bottles containing it in a sauce-pan of water, and causing the water to boil for about a quarter of an hour; when this has been done, remove the bottles, and when quite cold cork them. Earthen-ware bottles are much less liable to crack during this process than glass bottles.

3657. *The aromatic vinegar* of the apothecaries is a preparation possessing an agreeable pungent scent or fragrant odour, that renders it peculiarly grateful and refreshing in crowded rooms and the apartments of the sick; and it affords relief in headaches, fainting fits, &c.; but its anti-epidemic qualities are only imaginary. It is said to be prepared by taking rosemary tops dried, and sage leaves dried, of each four ounces; lavender flowers dried, two ounces; bruised cloves, two drachms; distilled vinegar, eight pounds; macerating these ingredients for seven days, and filtering the expressed liquor through paper. Some add camphor. What is met with in the shops, under the name of "salts of vinegar," is nothing but sulphate of potash put up in small vials, and impregnated with acetic acid, made aromatic with oil of rosemary or lavender.

SUBSECT. 5.—*Preservation and Purifying of Vinegar.*

3658. *The preservation of vinegar* is an object of consideration. In the way in which it is usually manufactured, it contains a considerable quantity of mucilaginous matters in addition to the acetic acid which has been formed; these are liable to farther change, and they pass at length into the putrid fermentation. If vinegar be long kept, and particularly if it be exposed to the air, it will become muddy and ropy, acquiring an unpleasant smell, losing its acidity, and putrefying. This last stage depends upon the same cause as the first, the presence of gluten, or some other substance that acts as a ferment.

3659. The methods of preserving vinegar are well described in one of Scheele's essays: "It is a fact generally known that vinegar, of whatever kind, will not keep long, but in the course of a few weeks, especially in the warm temperature of summer, grows turbid; its surface is then covered with a thick, mucilaginous substance, during which time the acid disappears by degrees, and at last is entirely lost; whence the vinegar must very often be thrown away. Now, in order to avoid this spoiling of the vinegar, five methods are known. The first is to prepare the vinegar very strong and sour at first, by using more sugar or other materials. It is well known that such vinegar will keep for several years; but as few people prepare their own vinegar, most persons contenting themselves with buying it at the shops, there are of course but few who can make use of this method. The second method is, to concentrate the vinegar by freezing; after which a hole is made in the crust of ice which covers it, through which the part that is not congealed is let out, and afterward put into bottles. This manipulation answers well enough; but nearly one half being lost, because that which forms the crust of ice is nothing, for the most part, but water, good economists dislike it. The third method is, to prevent the access of air, by filling the bottles full, and keeping them corked. Though vinegar is kept long by this method, it is not much employed, probably because it is troublesome to fill up the bottle with clear vinegar from another bottle every time you have made use of part of its contents. The fourth method is, to distil the vinegar, and thus leave behind the impurities. Distilled vinegar does not suffer the least change, though exposed to a warm air for years; but the expense of distilling is often thought too much."

3660. *The following method of purifying vinegar is the easiest, and answers sufficiently:* Put the vinegar into a well-tinned vessel, and make it boil for a minute over a strong fire, or the vinegar may be put into bottles, and then into a kettle of water upon the fire, and boiled; this will coagulate the glutinous and mucilaginous matter which all vinegar contains, and this may be separated by straining; after which the clear liquid should be kept in well-corked bottles. Vinegar prepared in this way keeps long without spoiling, and should be so treated when intended for pickling vegetables.

3661. *To render pickling vinegar colourless*, which is necessary for some kinds of pickles, stir together one gallon of the best pickling vinegar and six ounces of bone-black (animal charcoal), and let the mixture stand at rest for two or three days; then decant off the clear vinegar.

3662. *If a vinegar be required of an extraordinary degree of strength*, a greater quantity of saccharine matter may be used in the first or vinous fermentation; but this will require longer time to acetify, and there are some peculiar difficulties in the process where much sugar is employed, which require considerable scientific skill; and still there is a great chance of failure. Vinegar and water, also, cannot be separated from each other by common distillation. To concentrate vinegar, therefore, after it is made, or to obtain a very strong vinegar by an easy process, has been a desideratum. One method of strengthening it is to dissolve some sugar in it, which, by its decomposition, changes into vinegar; for, after some weeks, the taste of the sugar has disappeared, and the strength of the vinegar has increased. The sugar must be added by little at a time, and the warmth of the place should be kept up; one of the advantages of wood vinegar is the great strength of which it may be had. See "Wood Vinegar."

3663. *Vinegar may be freed from most of its impurities by distillation;* the acetic acid, which forms the basis of vinegar, is very volatile. When vinegar is distilled till about two thirds, or rather more, has passed over, nearly all the impurities are left behind as empyreumatic matter, remaining in the still; and the product of the distillation is acetic acid, almost quite pure, but diluted with water, which has come over with it. This is called *distilled vinegar.*

3664. *Distilled vinegar* is colourless, and of an odour somewhat different, but less agreeable than that of common vinegar. It may be preserved for any length of time without alteration in close vessels. When exposed to moderate heat, it evaporates completely, and without undergoing any change in its properties. By the action of severe cold, the watery part congeals, and separates from the pure acetic acid, which may thus be obtained in the highest state of concentration. Chemists have also other modes of preparing the pure acid, but these are of a nature rather complicated. Distilled vinegar is only employed for pharmaceutical purposes, and for perfumes; for it would be too expensive in domestic economy, neither would its flavour be agreeable as a condiment. It is sometimes improperly called acetic acid, for the latter contains no water.

3665. *Pure acetic acid is prepared from distilled vinegar.* It has an extremely pungent odour. Its taste is eminently acid, and it excoriates and blisters the skin when applied to it. It is so volatile, that it is converted into vapour at a very moderate temperature, without undergoing any change; and its vapour is inflammable, and burns with a white light.

It is pure acetic acid that gives sourness to every kind of vinegar, which consists of water, mucilage, and a certain quantity of this acid, greater or less, according to its degree of sourness; and it is this which is always generated by the acetous fermentation.

It exists ready formed in the juices of many plants, combined with potash and lime; but the quantity is never sufficient to render it available for domestic purposes. The strongest kind of common vinegar contains about five parts acetic acid in every hundred parts.

By its flavour, odour, and volatility it is easily distinguished from all other acids: when diluted with water, it is the same thing as distilled vinegar; its chemical constitution is, that it consists of oxygen, hydrogen, and carbon; the latter element in the proportion of 47 per cent., and the other two in the exact proportion necessary to form water; but we must not consider it as consisting of carbon and water, for oxygen and hydrogen compose water only when they are combined together in a certain proportion, *without any other element.*

Subsect. 6.—*Wood Vinegar.*

3666. It was formerly thought that acetic acid could only be prepared from liquors which had undergone the acetous fermentation; but it is now known that fermentation is not essential to its formation by art, since it can be procured by the destructive distillation of any vegetable matter, such as wood. But it must not be supposed that vinegar exists ready formed in wood, though we have stated this to be the case in small quantities in many sour plants.

3667. *The formation of wood vinegar depends upon principles which can be explained by chemistry,* and furnishes an interesting instance of its application; for it must appear extraordinary to those hitherto unacquainted with the fact, that an acid such as vinegar can be distilled from an insipid material like common wood. But the theory of it will be easily comprehended by those who have perused what we have said upon the component parts of vegetables, and the possibility of the conversion of one proximate principle into another. Vinegar, or acetic acid, consists of certain proportions of oxygen, hydrogen, and carbon: these elements are contained in wood; and it is obvious that if they could be detached from their combinations in the wood, and re-combined in that particular proportion requisite to constitute acetic acid, we should procure this liquid. Now this is effected simply by the application of a considerable heat to the wood confined in a closed vessel having a tube proceeding from it in the manner of a retort, or a distilling apparatus. In this, when placed in a furnace, the wood is decomposed into its elementary principles, which then recombine in another manner; one of the products of this new combination being acetic acid.

The process is extremely simple, and is employed to a very great extent. Nor is this, although but lately put in practice for making vinegar for common use, a new discovery; for it was known two centuries ago to Glauber, the chemist, whose name is attached to a well-known salt; and as this is a curious example of discoveries made and neglected, we may quote his account of wood vinegar in his work entitled "*Miraculum Mundi*:" "If the juice of wood be rectified, it may be used in the preparation of good medicines; in mechanic arts; in the making of many fair colours from the extraction of metals, minerals, and stones; and for all things for which common vinegar is used; yea, far more commodiously, because it much exceedeth common wine and beer vinegar in sharpness."

Apparatus of a great variety of form have been constructed by various manufacturers of wood vinegar for the purpose of producing it; but the principle of all is the same. The wood is put into a cylindrical iron retort laid horizontally, placed in brick-work, and with a fire beneath; from this vessel proceeds a tube, which terminates in a worm placed in a cistern of cold water; when the fire is lighted and the wood heats, the water which naturally existed in it first rises as steam; and, being condensed in the worm, falls into the receiving vessel, drop by drop. But when, by the continuance of the heat, the vessel becomes red-hot, the wood begins to be decomposed, and some of its oxygen and hydrogen unite together, and compose water, which likewise comes over. This water soon begins to taste acid, which demonstrates the commencement of the formation of vinegar by part of the carbon also separating, which, joined to the oxygen and hydrogen, compose that acid.

The acetic acid, however, does not in this manner come over quite pure; for it is mixed with a considerable quantity of a dark-coloured oil, or tar, which becomes thicker as the process goes on, and which is another product of the decomposition of the wood; this partly floats, and partly sinks in the liquor. Together with these, carburetted hydrogen, or imflammable gas, and some other gases, are generated abundantly. The acidity of the liquor continues to increase, but is somewhat disguised by the strong taste and odour of the tar, which gives it a reddish-brown colour. The whole of what then comes over, water, acetic acid, and tar, is called, in commerce, *rough* or *crude pyroligneous acid*, or the acid of wood, which received this name from its being supposed to be a peculiar acid; but chemists have since found that, when purified, it is actually acetic acid. The carbon that does not come over remains in the still in the state of charcoal, preserving the form of the wood first put in.

The wood employed must not be of the resinous kinds; but any refuse spray of other species will do: the densest wood is the best. In the late improvements in the process, the water of the wood is dissipated by heat in the forest where it is cut, before it is put into the retort, and other improvements are made in the apparatus, which it is not necessary for our purpose to specify. The crude pyroligneous acid is rectified by a second distillation, by which much viscid tarry matter is left in the still, and it is now a transparent brown vinegar, but having a strong, smoky flavour, from a slight admixture of empyreumatic oil.

3668. *A very pure vinegar* is obtained by saturating the rectified pyroligneous acid by quicklime, evaporating the acetate of lime thus formed to dryness, and destroying the empyreumatic matter by gentle torrefaction, which leaves the acetate of lime pure: the lime is now removed by adding sulphuric acid, which attracts the lime more strongly than the acetic acid, forming sulphate of lime; and in this manner this latter acid is procured similar to that which is prepared by the acetous fermentation already described. When well prepared, it has no peculiar taste nor smell; it contains no vegetable gluten nor mucilage, &c., and is therefore purer than the vinegar from malt, sugar, fruit, or wine.

It succeeds well as a pickling vinegar, because it may be concentrated to any degree of strength. At Beaufoy & Co's., Lambeth, there is a manufactory of wood vinegar on a large scale, where it is prepared quite colourless, and of such strength that, when diluted with seven times its weight of water, it makes the distilled vinegar at present employed by the apothecaries, and is used by some as the best pickling vinegar.

3669. *The pyroligneous acid* which comes over first, in its unpurified state, possesses the remarkable property of preventing the putrefaction of animal substances; it is well known that meat that has been smoked keeps better than that which was dried without smoke; and it is now ascertained that this effect depends upon the pyroligneous acid that rises with the smoke of the wood or turf which is employed in smoking it. This subject will be considered when treating on the "Preservation of Food."

3670. *A peculiar liquid called wood spirit*, or *pyroxylic spirit*, is procured in the second distillation of the pyroligneous acid, for the purpose of obtaining the pure vinegar from it. This wood spirit considerably resembles ether, but differs from it. Like ether, it dissolves Indian-rubber, and is used in making the water-proof cloth; it also dissolves resins, and, being cheaper than alcohol, is employed in the manufacture of water-proof hats. It is colourless, and highly inflammable, so as to be employed in lamps instead of spirit of wine. It was discovered by Mr. P. Taylor in 1812, and is manufactured by Messrs. Turnbull and Ramsey of Glasgow.

Subsect. 7.—*Adulteration of Vinegar.*

3671. *Vinegar, like most manufactured articles of food and drink, is frequently adulterated.* One of the most frequent sophistications is the addition of some cheaper acid, to increase the strength of the vinegar, as the sulphuric or nitric acids.

3672. *Sulphuric acid in vinegar may be detected* by the nitrate of barytes, or even by the acetate of lead, each of which will occasion a white precipitate if the vinegar contains this acid. To detect nitric acid, pour a little of the vinegar in a watch-glass, and add a few drops of muriatic acid; then put a small piece of gold leaf into the mixture, and if nitric acid be present, the gold leaf will be dissolved; the reason of which is that gold is only soluble in the nitro-muriatic acid; but, by the addition of muriatic to the nitric in the vinegar, the nitro-muriatic is produced. It must be observed, however, that the manufacturer is allowed by law to add to his vinegar one-thousandth part of sulphuric acid; but this prescribed quantity is often exceeded.

3673. *Vinegar is frequently made of too little strength, and, to conceal this, acrid substances* are added, as pimento, mustard-seed, and pellitory of Spain. To detect these, mix some of the suspected vinegar with carbonate of potash till the acid taste is totally destroyed, and then the burning taste of the acrid substances will be perceived, whereas pure vinegar leaves a sense of cold; or evaporate a little of the vinegar to be tried in a watch-glass or saucer, and likewise a little vinegar known to be pure; by touching with the tongue what remains, the hot substances will be discovered.

3674. *To ascertain the strength of vinegar*, find how much chalk or marble powder it will dissolve with moderate heat. As a guide, good wine vinegar will dissolve rather more than the twelfth part of its weight of carbonate of lime. It will dissolve less in proportion as it is weaker. By observing how much any good vinegar will dissolve, it is easy to compare any other sample with it.

3675. *Various substances are used to flavour vinegar, as condiments;* thus we have cucumber vinegar, capsicum vin., garlic vin., shallot vin., onion vin., caper vin., cress-seed vin., celery-seed vin., truffle vin., Seville orange-peel vin., ginger vin., black pepper vin., white pepper vin., Chillie vin., horse-radish vin., tarragon vin., basil vin., green mint vin., elder-flower vin., celery vin., Cherville vin., Burnet vin., orange-flower vin.; all these are made by steeping about an ounce of the several articles each in a pint of the best vinegar for fourteen days, and straining; it is then bottled. For the particular receipts for making them, see the article "Flavouring Ingredients," under the Section "Cookery." The wood vinegar, or crystal vinegar of the shops, is the best for receiving flavours, having scarcely any of its own.

CHAPTER VII.

ON THE PRODUCTION OF COLD, PARTICULARLY FOR COOLING LIQUIDS, AND THE CONSTRUCTION OF AN ICE-HOUSE.

3676. *The cooling of liquors in domestic economy has at all times been a practice* of general prevalence in warm countries, and during the heat of summer even in colder climates. When the temperature of the air is above 70°, cooled liquors become not merely a luxury, but are considered in some countries as an article of the first necessity. The langour which is induced by heat is, in a great measure, relieved by artificial cooling; and invalids, in many cases, receive great benefit from the use of cooled liquors.

3677. *The custom of preserving snow during the summer for this purpose* has prevailed among Oriental nations from the earliest ages. In the Book of Proverbs we read, "as the cold of snow in the time of harvest, so is a faithful messenger to those who send him; for he refreshes the soul of his masters:" and we learn, from various passages in the writings of ancient authors, that the Greeks and Romans were long familiar with this luxury. In the time of Seneca, snow collected from the mountains, and preserved in deep pits, had become an important article of merchandise in Rome, was sold in the shops, and even hawked about the streets.

The following passage from Mr. Lumisden's "Remarks on the Antiquities of Rome" describes the present method of managing this matter: "A little above Rocca di Pappa (on the ancient Mons Albanus) is a plain called Hannibal's Camp. It is here that the snow is collected annually for the use of Rome. On this dry plain they dig pits, without any buildings, about fifty feet deep, and twenty-five broad at top, in the form of a sugar-loaf or cone. The larger the pit, the snow, no doubt, will preserve the better. About three feet from the bottom they commonly fix a wooden grate, which serves for a drain if any of the snow should happen to melt, which otherwise would stagnate, and hasten the dissolution of the rest. The pit thus formed, and lined with straw and prunings of trees, is filled with snow, which is beat down as hard as possible, till it becomes a solid body. It is afterward covered with more prunings of trees, and a roof raised in form of a low cone, well thatched over with straw. A door is left at the side, covered likewise with straw, by which men enter and cut out the ice, for such it becomes, with a mattock. The quantity daily demanded is carried to Rome in the night-time in carts well covered with straw. It is found by experience that snow thus pressed down is not only colder, but preserves longer than cakes of ice taken from ponds or ditches."

3678. *The use of snow to cool liquors at the tables of the great* does not appear to have been common in any country, besides Italy and the neighbouring states, before the end of the sixteenth century. At that time there were no ice-cellars in France. But, towards the end of that century, under the reign of Henry III., this refinement was well known at the French court; and although, at first, it was considered as a mark of excessive and effeminate luxury, it soon became general in France, and towards the end of the seventeenth century dealers found the sale of snow and ice a profitable trade.

3679. *The method of improving the cooling power of snow by mixing with it various salts* is a modern invention. The Italians were the first by whom it was employed. About the year 1550, all the water as well as wine drunk by the wealthy in Rome was cooled by a mixture of snow and saltpetre, and afterward common salt was substituted for the latter. Lord Bacon, who died in 1626, was acquainted with the cooling properties of snow with saltpetre, or with common salt, so as to freeze water, but says that he had never tried the experiment. Soon after this time the French made the discovery in the art of cookery of congealing by cold a variety of agreeable juices, and of forming ice-creams and other luxuries of that class.

3680. *The most ancient method of using snow or ice* was by putting a small quantity of it into the liquor to be drunk; but afterward a more elegant method was employed by putting the beverage into a vessel of thin glass or metal, and surrounding this with the snow.

3681. *In the south of Italy and Sicily, at present, iced water is become an article of prime necessity,* and is sought for at all seasons, both in summer and winter, with an avidity which, to a native of a northern clime, appears, at first view, quite unaccountable. Snow for this purpose is preserved in several caverns in Etna, and is brought down from the mountain to be sold in the shops, which are often surrounded by a clamorous mob of purchasers, who express an eagerness to procure it that naturally excites the astonishment of an Englishman. Ice is now transported in ships from cold to tropical countries; and a cargo of it carried to India or South America is not uncommon.

3682. *Various methods have been employed for the production of artificial cold.* The methods at present in use may be reduced to three: 1, the application of some body naturally colder than that to be cooled; 2, by evaporation; 3, by the solution of certain saline substances. Sometimes two or more of these methods are combined to increase the effect.

3683. *For the first method, the use of ice and snow is the most generally practised;* and for this purpose they are preserved in ice-houses, or other proper places for cooling liquors in the summer, or during the whole year. A little ice, placed round a bottle of water or wine, in any convenient vessel (wood is the best material, as being the worst conductor), soon cools it to the desired degree; and, if the effect is to be increased, so as to freeze creams, fruit, &c., by breaking the ice into small pieces, or pounding it, and mixing common salt with it, the desired end will be accomplished. This method is employed by the confectioners. The principle upon which ice cools any liquor is, that it abstracts heat from every body surrounding it, till the temperature of the whole is equalized; and, of course, it melts itself in cooling other bodies, the heat which it takes from them being necessary to render it fluid; this heat becomes latent in the melted ice. See "Heat," Book II., Chap. I.

3684. *When ice is used to cool wine,* it will not be very effectual, if applied, as is sometimes the case, only to the bottom of the bottle; for the coldest part of the liquid, being already at the bottom, cannot ascend; nor can the upper part, which is the warmest, change places to be cooled; therefore no motion can happen in the wine, and the cooling will therefore be very imperfect. To cool the wine effectually, it is necessary to plunge the whole bottle in ice; but, before this is done, it is proper to decant it into a fresh bottle for the following reason: If there be any sediment in the wine that is of the same specific gravity, it will mix with it as if it had been shaken, from the up and down currents that always take place during the cooling.

3685. *When ice cannot be procured, well water forms a useful substitute to a certain degree.* A well of about forty or fifty feet in depth constantly preserves the mean temperature of the country, and, consequently, is colder than the summer heat of the place, hence, if a pail of water be drawn, and a bottle of wine or other liquor be immediately placed in it, it may be cooled considerably. In London, where the heat of summer may be above 65°, or even 70°, the temperature of well water will always be 50°; therefore, by this alone, liquors may be sometimes cooled 12° or 15°.

3686. *One of the most general and useful modes of cooling is by evaporation.* When any liquid is converted into vapour, a certain quantity of heat to be combined with it is necessary for this purpose, and the portion which rises in vapour abstracts caloric from the mass, which is, consequently, in proportion cooled. Any substance which is wetted with water, and kept in the air, will therefore be cooled by the evaporation of the water, and the more rapidly if it is held in the wind, because then the evaporation will be greater by the succession of particles of air, each carrying off so much heat. Take two thermometers, and wet the bulb of one, and not the other; hold them in the air, and the mercury in that only which is wetted will fall, through the cold produced, as the bulb dries. If a liquid be used that evaporates more quickly than water, as spirit of wine, and still more, ether, the cold produced will be more considerable.

Cooling by the wind is a method that can be employed only occasionally. If any part of the naked body, as the hand, be exposed to the wind, it will be cooled, because there is an evaporation from the surface. A practice among sailors for telling which way a very gentle breeze blows in the night is founded upon this fact. They wet a finger all over, and hold it above their head; the side that is most cooled is that which the wind blows upon, and, of course, points to the quarter from whence it comes. Should, however, the current of wind be warmer than the body it blows against, the latter will be heated, as is the case with the hot winds from sandy deserts.

3687. *As an example of the various degrees of cold occasioned by the evaporation of different substances,* we may cite the result of some experiments made by M. Cavallo, and described in the "Philosophical Transactions," 1781.

A small stream of several liquids was poured upon the bulb of a mercurial thermometer when the temperature of the atmosphere, and, consequently, of the thermometer, was at 64°. Water lowered the thermometer to 56°; spirit of wine to 48°; spirit of turpentine to 61°; olive, and other oils that do not evaporate, did not affect the thermometer; ether reduced the thermometer to 20° below the freezing point; and with a small bulb, it required only twenty drops of ether to produce this effect in ten minutes. If a small, thin glass tube be filled with water and wetted with ether, the water will be converted into ice in a minute or two, from the rapid evaporation of the ether.

The practice of cooling on this principle has been known from time immemorial. It is a common thing in the southern parts of Europe to wrap up a bottle of wine, water, or other liquor required to be cooled, in a wet cloth, and thus to suspend it in a shady place, either under a tree or in a passage, so as to expose it to the briskest current of air that can be obtained; by this means the liquor will be cooled several degrees; care must be taken to sprinkle more water upon the cloth which surrounds the bottle in proportion as the former evaporates. In India it is the general custom, in order to keep the wine cool, to clothe the bottles in wetted cloths fancifully ornamented with flowers, and to cause them to make the circuit of the table in this grotesque dress, instead of pouring the wine into decanters. Port, Claret, and Burgundy are characteristically attired in crimson with white flowers; while Sherry and Madeira appear in bridal costumes. It is upon this principle, namely, the cold produced by evaporation, that persons sustain much injury by sitting in wet clothes.

3688. *Vessels called Alcarrazas* are much employed in Spain for cooling water, and there is scarcely a house in that country where they are not in constant use. What distinguishes them from other kinds of earthen-ware is their porosity, which is so considerable, that being filled with water, the liquid oozes slowly through, and stands in minute drops, like dew, on the outside; this evaporates and produces cold, particularly when the air is warm, or when there is some wind. This loss of heat from the outside is supplied from the water within the vessel, and the continued evaporation produces more and more cold; and the agreeable coolness thus given to water in a warm climate is extremely grateful. These vessels appear to have been introduced into Spain by the Saracens, and their use has since been extended to all the Spanish colonies in America and India. Vessels of a similar kind have, however, been known from time immemorial in China, Hindostan, Persia, Arabia, Egypt, and Syria.

The most celebrated manufactory of this kind in Spain is at Anduxar, in Andalusia, the best earth for the purpose being found on the banks of the River Tamusoro. After being well tempered, it is mixed with a little salt, and the heat in baking is not so great as to render the salt insoluble in water; the salt being dissolved out, produces the necessary porosity in the vessels.

In the neighbourhood of the convents of Vittoria, near Malaga, the country people find a useful clay, of which they make the large red jars called *beccaras*, used for cooling water, though inferior to the alcarrazas. Without these contrivances the inhabitants of these sultry shores would be deprived of one of their most essential luxuries.

The dryness of the air in these climates, and particularly in Italy and Egypt, causes it to absorb moisture rapidly, and hence assists the refrigeration; but the same vessels, having been brought over to this country, have been found to cool the contained liquor only in a very trifling degree, owing to the state of the air in Britain, which is much less hot, and much less dry than in the above-mentioned places, therefore much less apt to promote evaporation. One of the Egyptian vessels was tried in London at a time when the temperature of the atmosphere was at a mean; and after about half an hour, when almost three quarters of the water had passed through it, and had dropped down, the remaining quantity was found barely 3° colder than the surrounding air.

3689. *Coolers of earthen-ware of a similar kind for wine or butter are manufactured in England*, and are at present to be found in many of the earthen-ware shops in London. They are made of a light-coloured, porous ware, and of elegant forms, with ornaments in bass-relief. Half an hour before they are to be used, they are put to soak in cold water, of which they will imbibe a considerable quantity. When wanted for use they are taken out of the water, and the decanter of wine placed in them. The evaporation from the surface of the cooler, of the water which has been imbibed, abstracts the heat from the air of the interior, and, consequently, from the wine. The cooling effect, however, not exceeding a few degrees, is seldom sufficient for wine. Some are made double, with a space between, for ice or ice-water. When these coolers want cleaning, a hard brush and a coarse cloth with sand only should be used; no soap should be employed.

3690. *The process of making ice in the East Indies* has been particularly described by Sir Robert Barker, Phil. Trans., vol. lxv. Natural ice is never seen in the warmest parts of that country. To procure ice by artificial means, they dig, on a large open plain, not far from Calcutta, three or four pits about thirty feet square, and two feet deep each; the bottoms of which they cover about eight inches or a foot thick with sugar-cane, or the stems of the large Indian corn dried. On this bed are placed, in rows, a number of small, shallow, unglazed, earthen pans, formed of a very porous earth, a quarter of an inch thick, and about an inch and a quarter deep; which, at the dusk of evening, they fill with soft water that had been boiled. In the morning, before sunrise, the ice-makers attend at the pits, and collect what was frozen in baskets, which they convey to the place of preservation. This is generally prepared on some high, dry situation, by sinking a pit fourteen or fifteen feet deep, lining it first with straw, and then with a coarse kind of blanketing. The ice is deposited in this pit, and beat down with rammers, till at length its own accumulated cold again freezes it, and forms one solid mass. The mouth of the pit is well secured from the exterior air with straw and blankets, and a thatched roof is thrown over the whole. The quantity of ice formed by the method above described depends on a light atmosphere, and clear, serene weather. Three hundred persons are employed in this operation in one place.

At first sight, this curious process may appear to be an effect of evaporation; but this is not the case; for it is remarkable that it is essential to its success, that the straw in which the vessels are placed should be dry; whereas, if evaporation were concerned in the congelation, wetting the straw would promote it. When the straw becomes wet by accident, it is obliged to be replaced by dry straw. The explanation of this process was involved in mystery till Mr. Wells published his celebrated observations on dew, which have afforded a solution of the phenomenon. The earth is continually losing heat by radiation, and it loses most on clear, starlight nights, when there are no clouds to intercept and send back the rays of heat. The straw, like all filamentous substances, is a good radiator of caloric, and it is in consequence of the heat that is thus given out by it into space on clear nights that the ice is formed. When the weather is windy and cloudy the effect does not take place.

3691. *The last method of cooling liquors that remains to be mentioned is obtained by the solution of salts.* It has been long known that certain substances generate a considerable degree of cold, particularly nitre, sal-ammoniac, Glauber's salt, muriate of lime, and several others. But most of these salts are so dear in Europe, that they are seldom made use of in this way, except in particular experiments, when it is wished to produce an intense degree of cold by a powerful freezing mixture.

In India, where nitre is very cheap, and the heat of the climate prompts the inhabitants eagerly to adopt every possibile method for counteracting it, the cooling of liquors for the table, by means of the solution of nitre in water, is very common. To effect this, the wine, water, or any other liquor, is put into a metallic bottle, generally a pewter one, having a pretty long neck. A tub is partly filled with water, and a quantity of nitre is thrown into it. Then the operator holds the bottle by the upper end of its long neck, and gently moves it about in the saline mixture while dissolving, which cools the liquor to a very considerable degree. As salts will produce cold only during their solution, when the first quantity has been thoroughly dissolved in the manner described, more nitre must be added; and when the water is completely saturated, so as not to be capable of dissolving more salt, the bottle, if to be cooled farther, must be removed to a tub with a fresh saline mixture. The nitre may be recovered again for the next day by exposing these solutions in shallow pans to the hot sun of that country.

3692. Sal-ammoniac would answer for this process; but a mixture of nitre and sal-ammoniac is the most effectual, by which a bottle of wine may even be cooled down to 32°. The best proportions are five parts nitre, five of sal-ammoniac, and sixteen of water. The solution by itself will lower in temperature several degrees below the freezing point; but when it has to abstract the heat from a vessel with wine put into it, it will not then become so cold.

3693. *In order to cool a bottle of wine in London* from the usual temperature, 50°, down to 32°, a pound of nitre, another of sal-ammoniac, and a proportionable quantity of water will be required; but to cool it to a considerable degree, half the quantity of salt will be sufficient; even this is too much for ordinary use, and mixtures of this kind in powder are sold in London for the purpose, by Mr. Fuller, of Jermyn-street, who likewise manufactures a useful freezing apparatus for making ice creams.

3694. *An intense degree of cold is produced by a mixture of snow and salt* in equal parts. The salt causes the snow to melt in consequence of the attraction which it has for water, even in the frozen state; and as they both unite, the snow is dissolved into water, and the water dissolves the salt, so that both become liquid. The cold thus generated is no less than 32° degrees below the freezing point, or down to zero of Fahrenheit's thermometer, and is a much more intense degree of cold than is required for the ordinary purposes of cooling liquids for beverage; but it may be useful to know how to increase the usual degrees of cold upon occasion. Pounded ice will do nearly as well as snow; any substance having a very strong attraction for water may be substituted for the salt.

3695. *If chloride of calcium (formerly called muriate of lime) be mixed with snow*, a still greater degree of cold will be produced; by this means 50° below the freezing point has been obtained, which is sufficient to render even mercury a solid mass; consequently, such a degree of cold can be measured only by a spirit thermometer, spirits of wine never freezing. The principle of this is the same as the last, the great attraction which chloride of calcium has for water.

3696. *No means have been discovered for depriving bodies of all their heat;* nor is it known what quantity they may still contain after these experiments. Intense degrees of cold like these act with the most destructive and rapid effect upon the living body; and to handle frozen mercury is described by those who have attempted it like touching red-hot iron; the skin would be destroyed, and the part become frost-bitten.

3697. *In using a freezing mixture* for ordinary purposes, it is sufficient to put it into a wooden vessel as a bad conductor, and then to place in that the vessel containing the liquid to be cooled. But when the most intense cold is wished for in an experiment, the vessel containing the mixture should be placed within another a little larger, being supported by corks, as in the wood-cut, *fig.* 566 (where the front of the outer vessel is supposed to be removed), and covered over with woollen cloth: the air in the space between the two vessels being a non-conductor, prevents the heat of the apartment from finding its way to the mixture, which, therefore, is obliged to rob the liquid to be cooled of its caloric.

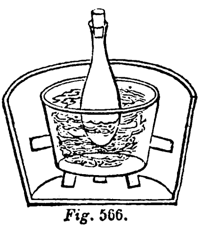


Fig. 566.

This mutual action of snow or ice and salt upon each other is well illustrated by the common practice of sprinkling salt upon a pavement that is coated with ice. The salt and ice soon dissolve and run off as liquid brine, or it may be swept off.

3698. *Mr. Walker of Oxford made a number of experiments in the production of cold* by various frigorific mixtures, and the results are published in the "Philosophical Transactions" for 1795 and 1801.

Mixtures of Salts without Snow.

Mixtures.	Parts by Weight.	Temp. falls from 50° to
Muriate of ammonia	5	10°
Nitre	5	
Water	16	
Muriate of ammonia	5	4°
Nitre	5	
Sulphate of soda	8	
Water	16	
Nitrate of ammonia	1	4°
Water	1	
Nitrate of ammonia	1	—7°
Carbonate of soda	1	
Water	1	
Sulphate of soda	3	—3°
Diluted nitrous acid	2	

Mixtures.	Parts by Weight.	Temp. falls from 50° to
Sulphate of soda	6	—10°
Muriate of ammonia	4	
Nitre	2	
Diluted nitrous acid	4	
Sulphate of soda	6	—14°
Nitrate of ammonia	5	
Diluted nitrous acid	4	
Phosphate of soda	9	—12°
Diluted nitrous acid	4	
Phosphate of soda	9	—21°
Nitrate of ammonia	6	
Diluted nitrous acid	4	
Sulphate of soda	8	0°
Muriatic acid	5	
Sulphate of soda	5	3°
Diluted sulphuric acid	4	

Mixtures of Salts with Snow.

Mixtures.	Parts by Weight.	Temp. falls to
Muriate of soda	1	—5°
Snow	2	
Muriate of soda	2	—12°
Muriate of ammonia	1	
Snow	5	
Muriate of soda	10	—18°
Muriate of ammonia	5	
Nitre	5	
Snow	24	
Muriate of soda	5	—25°
Nitrate of ammonia	5	
Snow	12	

Mixtures.	Parts by Weight.	Temp falls to
Diluted sulphuric acid	2	—23°
Snow	3	
Concentrated muriatic acid	5	—27°
Snow	8	
Concentrated nitrous acid	4	—30°
Snow	7	
Muriate of lime	5	—40°
Snow	4	
Crystallized muriate of lime	3	—50°
Snow	2	
Fused Potash	4	—51°
Snow	3	

The snow should be just fallen, dry, and uncompressed.

By first cooling the materials before they were mixed, through immersing them in other frigorific mixtures, Mr. Walker obtained a degree of cold 100° below zero, the greatest degree of cold ever produced.

3699. *A method invented by Professor Leslie of producing artificial cold, and freezing water,* depends upon the principle that water evaporates much more rapidly when the pressure of the atmosphere is withdrawn, as in the exhausted receiver of an air-pump. If some material be included in the receiver that absorbs vapour, the evaporation will proceed with still greater rapidity, and, consequently, a greater degree of refrigeration will take place. Sulphuric acid, which has a great absorbent power, is poured into a shallow dish to the depth of half an inch, in which is placed a small vessel with water that has lost its air by boiling; the whole is then placed under the receiver, and most of the air extracted. By the rarefaction of the air, the water evaporates very quickly, and its vapour is absorbed as it forms by the acid, so that in a few minutes the remaining water is frozen into a solid mass. The loss of water seldom amounts to a fifteenth part, nor is it till after repeated use that the sulphuric acid becomes so weak as not to effect the absorption. The acid can thus effect the congelation of more than twenty times its weight of water.

Mr. Leslie varied this process by substituting pounded trap-rock, well dried before the fire, instead of the sulphuric acid. This powder, by the same property of absorbing aqueous vapour, was able to freeze the sixth part of its weight of water. He also found that parched oatmeal was a convenient and powerful absorbent; and by means of the air-pump with a body of oatmeal of a foot in diameter, and rather more than an inch deep, he froze a pound and a quarter of water contained in a hemispherical porous cup. The oatmeal, which is less hazardous than acid to those little used to experimenting, is easily dried and restored again to the same action. It would appear from this experiment that, with an air-pump, it would be easy to procure ice in a hot climate, or at sea.

3700. This method of keeping the air in a vessel constantly dry by an absorbent substance is not only useful in producing cold, but also in drying many articles; and it has lately been in much use for the latter purpose.

3701. *The principle of preserving ice itself* depends upon surrounding it with what are termed *non-conducting* substances, or substances which heat cannot pass through, for an account of which we refer the reader to Book II., Chap. I., "On Heat." This is necessary in order to defend it from the common air of a temperature above the freezing point, and from moisture of water, which must necessarily be warmer than 32°.

If ice could be kept always from the contact of other bodies of higher temperature than itself, or be surrounded by substances which heat could not pass through to reach it, it must always remain in the same state. But we know of no substances that are *absolute* non-conductors, and certain bodies receive that name only because heat passes them with very great difficulty. The substances of this kind are chiefly air, water, and materials of loose and porous texture, as wool, straw, charcoal, cork, wood, &c. Metals and hard stones allow heat to penetrate them with most facility, and consequently they are conductors of heat.

3702. *The method of transporting ice and snow to a distance is very simple;* it is only necessary to enclose them in some substances that are good non-conductors, as chaff, straw, woollen, &c.; and if the package be put into a box an inch or two larger, and wedged in with pieces of cork, this would be a still farther security, when the quantity is small. It is in this manner that the Neapolitan peasants carry snow from the repositories on Vesuvius to Naples during the heat of summer.

3703. *Ice preservers* are chests of stout deal lined within with cork, as being a bad conductor of heat; into these a quantity of ice is put, to prevent going frequently to the ice-house. Ice may be kept in them for three weeks in summer. If cork cannot be got easily, the sides of the ice preserver may be made double, with a space of two or three inches between, which space should be filled with charcoal reduced to powder, than which no better non-conductor is known.

3704. *Ice pails* are likewise kept for icing creams, cooling wines, butter, &c.

3705. *Ice may be kept in the open air for a year* by making a pile of it on dry ground (the north side of a hill is the best place), in a steep, conical form, of considerable size in winter, during a hard frost, and covering it over, first, a foot thick with a layer of fagot wood, then with another layer of straw, and, lastly, thatch. This should be placed on an elevated mound, or platform raised on purpose, that the water may drain off from it. If shaded by trees, or a shed roof, so much the better. If the pile be sprinkled occasionally with water while it is building, in frosty weather, the water will, by freezing, cement the masses of ice together, and make them last longer. The steeper the conical pile is made, the better.

3706. *Ice may also be preserved in cellars*, which should have no windows, and be provided with double doors. The floor and sides of the cellar should be lined with straw; or a better method would be to form a framing of bars of wood for the floor and sides, insulated, and covered with straw.

ICE-HOUSE.

3707. It has long been the custom here to connect the subject of an ice-house with that of the dairy; and where the former is entirely detached, and at some distance from the house, the two may very properly be associated. The most useful mode of constructing an ice-house is the following:

A well is sunk in the ground in the form of an inverted cone, *a b* (*fig.* 567), which is lined with brick-work of a brick and a half thick, and arched over. Into this the ice is put, through an opening *g*, left in the top of the arch. A door is made on one side, *c*, for taking out the ice, or putting things in, and a drain, *d e*, is constructed from the bottom to carry off the water which is formed by the melting of the ice in summer. The advantage of the conical form of the well is supposed to be, that as fast as the ice thaws the remainder slides down the sides of the cone, and still keeps in a compact body. Another advantage is, that the circular form of the cone is stronger than a square or any other shape, thus resisting better the pressure of the earth.

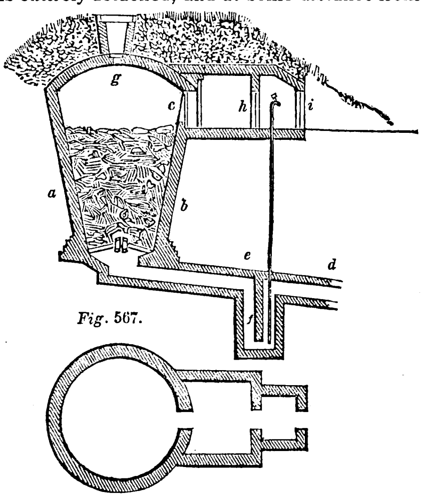

Fig. 567.

Some recommend to have the brick lining double, with an empty space between, to form a more complete non-conductor of heat; but this additional expense is unnecessary under ground. The draining is essential, some ice-houses failing through want of attention to it.

The walls of the cone should be built with Roman cement, or, at least, with very good mortar that will set hard. To support the ice at bottom, it should be placed on a strong wooden grating, or, what is found to answer very well, an old cart-wheel, as represented in the wood-cut, being very strong from its form: this permits the water produced by the partial thawing of the ice to pass off into the drain, *c d*; the latter should have a trap, *e*, to prevent the external air from communicating with that of the ice-house. Should the situation of the ground not admit of a drain being carried out from the bottom of the ice-well, it may terminate in a small well, *f*, sunk deeper to receive the water; and as this water will always be ice-cold, it may be raised up, when wanted for cooling wine, butter, &c., by a small pump placed in the porch of the ice-house.

The door for taking out the ice, *c*, should be double, with straw stuffed between both; and the same precaution should be used with the aperture, *g*, for putting in the ice. There should be a long passage leading to the door, *c*, having in it two more doors, *h* and *i*. In the space between *h* and *c* there may be an ice-cold room; and the space between *h* and *i* is to admit of the door *i* being shut before the door *h* of the cold room is opened, to hinder the access of the external air. The top of the ice-house may be finished in various ways. It may be covered over with tough clay, and then with earth, and planted with shrubs as a mound ; or it may appear as a low building covered with plenty of thatch. The closer the ice is packed the better.

3708. *An ice-house may be formed above ground* by building the walls and arched roof double, a foot apart, the better to keep out the heat ; and the whole may be thatched, or covered over with giant ivy, or some other creeping plants. The ice should be laid hollow, with a drain from it, and all the precautions above mentioned taken. When ice cannot be had, snow packed and beaten down well may serve as a substitute.

3709. *A succedaneum for an ice-house* may be made as follows: Take an iron-bound butt or puncheon, and knock out the head ; then cut a small hole in the bottom about the size of a wine-cock ; place inside of it a wooden tub having a similar hole, resting it upon three pieces of wood, which are to keep it from touching the bottom ; fill the space round the inner tub with pounded charcoal, and fit to the tub a cover having a convenient handle ; place on the lid a circular flat bag of pounded charcoal about three inches thick, that will cover it entirely, and over all put another wooden cover. When this apparatus is prepared, bury it for four fifths of its height in the earth of a cold cellar that is dry, keeping it a few inches from the earth at the bottom by means of pieces of bricks. Fill the inner tub nearly with ice or snow beaten hard down, leaving room to place any vessel holding the substances to be iced. When the cover is taken off to place these in, care must be taken that it is replaced when the icing is finished ; the congelation will, in general, be effected in half an hour.

3710. *In London, ice is sometimes supplied to the confectioners* almost daily in the summer from ice-cellars kept by persons who make this a business, and carry the ice round to the shops in carts. The ice is then put into a large tub in the cellar. The ice-creams are made there in pewter vessels about a foot in depth and three inches in diameter; these are brought up into the shop, and placed in a wooden reservoir full of ice, with a cover, to supply customers.

3711. *Ice-cold rooms* would be found useful additions to the domestic offices of a mansion. They might be connected with the ice-house, which should be considered as the focus of cold, and should always have double doors, double windows, and the walls should be built hollow for the purpose of preserving an even temperature. A small inner room might have a well to contain ice; thus several degrees of cold might be obtained by different apartments. The usual idea of an ice-house in England is, that it must be a detached building at a little distance from the house ; but, though this situation has some advantages, yet it is not absolutely necessary ; and it might often be more convenient to connect it with the pantries, or to place it in a cellar to which access might easily be had.

3712. *There are some curious facts respecting the freezing of water*, which, although not essential to our subject, it may be interesting to notice. This process begins by numerous minute spiculæ appearing and shooting across the surface of the water, and always making angles with each other of 60° and 180° ; as these accumulate, the ice becomes more solid ; but its specific gravity is always one ninth less than that of water, in consequence of which it floats. Water, in cooling, becomes more dense, not at the freezing point, 32°, as might be expected, but before it arrives at that point, as at about 39° ; and in cooling still farther down to 32°, it actually expands, so as to be at the same degree of density as it was at 35°, expanding equally by cooling or heating below or above 38°. If water be exposed to cold and agitation, it cannot be cooled below 32° without freezing ; but if the water be kept quite still in a large vessel, it may be cooled down to 25°, considerably below the freezing point, without becoming ice ; if, however, any tremulous motion takes place, it instantly freezes, and the temperature then suddenly rises to 32°. If water be confined in the bulb of a thermometer, it is very difficult to freeze it by any cold mixture above 15° ; but, if the cold be below that, it cannot be prevented from freezing. When cooled down to 15°, the water in the bulb remains perfectly transparent ; but, if it accidentally freezes, the congelation is instantaneous, the bulb becoming in a moment opaque and white like snow, and the ice is projected up into the stem. The freezing of water is an actual crystallization, and these facts depend upon the laws which regulate that natural process.

The expansion of ice in forming is a phenomenon of great importance, and is attributed to the mode of the crystallization, and not to the ice enclosing air ; for water parts with its air on becoming ice, and on this account it is that water freezes sooner for having been boiled. Boiled water affords the most compact and beautiful ice.

3713. *Water which has just been produced from melted snow or ice* is very nearly as cold as the ice itself before it began to thaw ; for although it may be easily supposed that it must have imbibed much heat in order to thaw, yet, by a singular fact in the economy of nature, this quantity of heat is not rendered sensible to the thermometer—a fact not only extremely curious, but very important to be understood. It is well known that ice may be much colder than the freezing point, but that, when its temperature rises to 32°, it begins to melt ; it melts very slowly, and is imbibing heat the whole time ; and yet, if the thermometer be put in among the thawing ice or snow, it will still indicate only 32°, nor will any difference be perceived until a short time after the whole has been thawed ; so long as any ice remains unthawed, no addition of heat will be perceived ; what, then, has become of all the heat that has undoubtedly been absorbed by the ice ? that heat has entered the ice, but only for the purpose of converting it into water ; and it remains in the water in what is called a *latent* state, so intimately combined with it that it cannot be separated, and is, in fact, essential to keep the water in its fluid condition ; if the water be deprived of this heat it freezes ; but, though the heat is given out again while the water is freezing, it is immediately carried off by the atmosphere and diffused, so as not to be felt. It is this gradual absorption of so much heat by melting ice that makes a thaw often colder than a frost.

3714. *Cold has been imagined to be something positive, like heat*, and that there are rays of cold like those of heat ; but this is an error. Cold is, in fact, nothing more than a very low degree of heat or temperature.

CHAPTER VIII.

ON THE VARIOUS SPIRITUOUS LIQUORS.

3715. The term *spirit* was formerly applied by chemists to all volatile substances collected by distillation. Three principal kinds were distinguished : inflammable or ardent spirits, acid spirits, and alkaline spirits; at present the name of spirit is almost exclusively confined to the first.

3716. The formation of ardent spirits (*fortunately*, we were about to say) cannot be considered as a necessary part of domestic economy, in its ordinary state in this country; and, therefore, perhaps the following account of it would not have found a place here, but from the obvious utility of understanding clearly the nature of all articles of domestic consumption, which it is impossible to do without referring to their mode of manufacture, and to the principles upon which their production depends. By this alone, likewise, we can be enabled to judge of the goodness or the bad qualities of the several articles.

Sect. I.—History of Ardent Spirits.

3717. Although the ancient nations were sufficiently acquainted with the art of preparing fermented liquors of various kinds, which necessarily contain alcohol or ardent spirit, and though they used many methods for rendering their wine more potent, yet they did not possess the means of procuring from it, in a separate form, the pure alcohol in which the intoxicating property resides.

Neither Pliny, who left a treatise on wine, nor any others of the ancient Greek and Roman authors who have written so much in praise of the fermented juice of the grape, make the least mention of its *spirit*, which certainly would not have escaped notice had it been known in their time. Galen, a century after Pliny, speaks of the aroma or essential oil obtained from fruits and flowers, but is silent on the distillation of ardent spirit. The discovery of the art of distillation, which may well be said to form an era in the history of mankind, appears to have been made by the Arabian alchemists of the twelfth century, in their search after the elixir of life. The art of extracting a spirituous liquor from wine was long kept a secret, and was in the sole possession of the physicians, who employed it only as a medicine, ascribing to it the most extraordinary properties, and among others that of prolonging life; hence the name of *aqua vitæ*. Brandy, or the spirit distilled from wine, was first produced, according to Le Grand, by Arnold de Villeneuve in Languedoc, as early as 1313, and it was then made into a liquor with aromatic spices. The art of distilling a cheaper spirit from malt was afterward discovered, and seems to have been better understood and more extensively practised in Ireland, at an earlier period than in England, where ale and mead were the favourite beverages; but the Irish "usquebach" appears also, at first, to have been a sort of liquor with aromatics. Whiskey is a corruption of *usque*, and in 1560 was made in the High lands of Scotland as well as in Ireland.

Sect. II.—General Principles of the Production of Ardent Spirits.

3718. *All kinds of spirituous liquors or ardent spirits*, whether brandy, rum, malt spirits, &c., owe their hot, fiery taste, their inflammability, and their intoxicating qualities to their containing more or less of the liquid called by chemists *alcohol*, a word of Arabian origin, which is spirit in its purest state, entirely free from water and other substances.

3719. It has been already shown, when treating on "Fermentation," Book VIII., Chapter II., that alcohol cannot be produced but by means of the process called *vinous fermentation*, or, as it might be named, the *spirituous fermentation;* and that it never exists ready formed by nature. When we hear, therefore, persons say, as they sometimes do, that there is a *spirit* in sugar, in carrots, or any other vegetable substance, we are to understand that such expression is not strictly correct; and that these substances only contain the materials from which spirit may be generated. The difference between brandy, rum, wine, ale, table-beer, and other liquors of this class, is merely that they contain different proportions of pure spirit, upon which their *strength*, that is, their intoxicating power, depends; and, likewise, that they have various proportions of water, mucilage, essential oils, and other flavouring matters, to which they owe their several peculiarities. The pure spirit which all these fermented liquors contain, and which may be extracted from them, is exactly of the same nature in each, though extremely different in quantity. This spirit, in the purest state in which *it is usually prepared*, is called *spirit of wine*, because it was originally procured from wine only; but it is now made from other liquors. This, however, is not the purest state of spirit, but contains a quantity of water.

We likewise stated that no substance can undergo the vinous or spirituous fermentation except it contain sugar or starch, which is capable of being converted into sugar; and that every vegetable containing either of these principles can afford a fermented liquor of some kind, that is, a liquor containing alcohol or spirit. If any fermented liquor is thus produced, no matter how weak, it will yield some spirit, more or less, by the process of distillation to be afterward described. It must, therefore, be kept in mind that, to produce spirit, the natural process of the vinous fermentation must be first resorted to; and, in order to separate the spirit so produced from the water and other matters with which it was mixed during the fermentation, the artificial process of distillation must be employed; in this, when the fermented liquor is put into the still, and heat is applied, the spirit rises, and is carried into the receiver, leaving the remaining portion behind. See "Distillation," Sect. III.

3720. *The vegetable substances most usually fermented for the production of ardent spirits* are, the various grains for malt spirit, the juice of the sugar-cane for rum, the juice of the grape for brandy, and potatoes, carrots, or other sweet vegetables for various spirits named after them. In other countries, the juice of the palm is employed, also rice for arrack, the juice of cocoanuts, and of the sugar maple: even milk fermented affords a spirit to the Tartars.

Sect. III.—distillation.

3721. *Distillation is the application of heat to a fluid* so as to make it boil or be converted into the vaporous state, and afterward condensing this vapour into a fluid again by means of cold. A familiar instance of this effect may be observed in a common tea-kettle; when it boils, steam, or the vapour of the water, is seen coming out of the spout; and if any cold body, as a plate, be held against this steam, it will be condensed upon it into drops of water. In the same manner, the steam may be conveyed to any distance by means of a tube, and may be condensed, where it is required, by the application of a cold body to the outside of the tube.

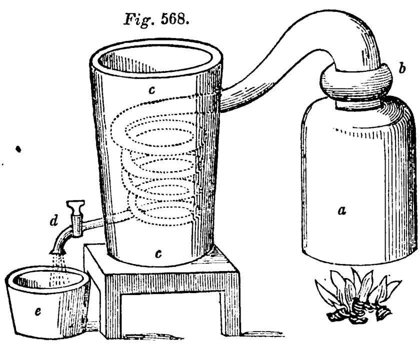
By means of this process of distillation, the most volatile of the component parts of a liquid may be separated from those which are more fixed by applying a degree of heat sufficient to convert them into vapour, and afterward condensing them, while the rest of the substance subjected to distillation remains behind.

3722. *Distillation is a process not solely employed in the formation of ardent spirit*, but is applied to many other purposes, as the obtaining the essential oils of vegetables, and even pure water.

All liquids boil, or become converted into vapour at a certain temperature; but various liquids require very different degrees of heat to make them boil; thus, water boils at 212°; alcohol at 176°; linseed oil at 600°; and mercury at 662°. From this it is evident that, if water and alcohol be mixed together, and put into a vessel over the fire, when the latter boils, the former will not be near the boiling point. The spirit, therefore, will rise in vapour at 176°, leaving the water behind; and thus these two substances may be separated from each other. But if no contrivance were used, the vapour or steam of the spirit would escape into the atmosphere and be lost; the method of condensing and collecting in a liquid form the vapour so raised is, therefore, an essential part of the art of distillation, and is effected by a particular construction of the distilling vessels.

3723. *The apparatus that has been most usually employed here for distilling is the still*, and although there are many improvements in this apparatus, it will be sufficient at present to describe the simplest: *a*, *fig.* 568, is a copper vessel called the still, into which the materials to be distilled are put; suppose water and spirit. The still is generally set or built up in brick-work, and a fire is made beneath it, as in the case of a washing copper; *b* is the head of the still, which takes off. When the heat is applied, *the spirit* will boil at 176°, as has been stated, and will consequently rise in vapour; and if the head of the still were off, this vapour would escape; but when the head is on, it is forced to pass through the bent tube, *c*, *c*, called the *worm:* now during this passage through so long a distance, it would be somewhat cooled, and partly condensed into a liquid, which would drop out at *d;* but, that this condensation may go on more rapidly, and none of the vapour escape uncondensed, the worm is made to wind in a spiral form many times round in a vessel kept full of cold water, called the refrigeratory, by which the condensation is more complete, and all the spirit raised in vapour by the boiler is obtained in the receiver, *e*, in a pure state, the water alone remaining behind in the still.

Fig. 568.



Sect. IV.—various kinds of ardent spirits.

Subsect. 1.—*Brandy.*

3724. *Brandy is produced by the distillation of wine only*, and not from any other fermented liquor; any spirits made from other liquors than wine *are improperly termed brandy.* But brandy consists not merely of the spirit drawn from wine; it contains also some water, and is flavoured by the essential oil of the grape, which has been dissolved by the alcohol produced during fermentation. As this essential oil, which rises with the spirit during the process of distilling it, is of a more agreeable flavour than that of malt or of molasses, genuine brandy, possessing this advantage, is very generally esteemed above every other distilled spirit.

3725. *Brandy is prepared in all the wine countries of Europe*, but particularly in France, where, however, the localities of the best French brandy are extremely limited. The grapes most proper for wines are not the fittest for brandy. All wines will yield a portion of this spirit; but the strong, heavy wines are in general preferred, on account of the quantity they give: in general, however, brandy is never distilled from wines that will fetch a good price, since the profits from the sale of these as wine are much higher than when reduced to the state of brandy. The weak wines often afford brandy of a fine flavour; those of Cognac and Andaye, from which some of the finest brandy is made, are the least drunk in France. The brandy of Cognac is not less than 60 per cent. better than that of Bordeaux, though the wines of the latter place are so much superior.

The brandies imported into this country are chiefly from Bordeaux, Rochelle, and Cognac; but they are inferior to those made in the neighbourhood of Nantes and Poictou, from whence private families in Paris, who are very choice in having the very best quality of the spirit, supply themselves.

The brandies of Spain, Portugal, and other wine countries of Europe are much inferior to those of France; but those of Spain are next in excellence.

3726. *Brandy varies in quality*, not only according to the mode of manufacturing it, but also from the difference that exists in the grapes, together with the soil and climate; and the variations would be still more considerable if every kind of wine was used for distillation.

The large proportion of small wines with which they are overrun in France accounts for their making such quantities of brandy more than in any other country; where the climate is warm, the grapes become sweet, and are often converted into raisins.

3727. *The general mode of preparing brandy is extremely simple*, being nothing more than a well-regulated distillation of wine in suitable vessels. At the commencement of the vintage, they collect all the grapes that are not fit for good wine, ferment their juices, and distil them for brandy; they also use for this purpose all wines that have failed in the making, although, if they have become at all acid, their brandy is tainted.

3728. *The art of distillation is far better understood in France* than in any other part of the Continent, and hence one cause of the great superiority of the brandies of that country. There is a great difference, however, in the flavour even of French brandies, according to the wine that has been made use of, and this is easily discriminated by good judges. Much also depends upon the care employed in the distillation, which originally was performed by means of large alembics, but of late several newly-invented apparatus have superseded these.

3729. *The process for making brandy in France* is as follows:

The still is filled three parts with wine, and very great attention is given to the management of the fire, that the liquid may remain at a uniform temperature. A small quantity of the product at the beginning of the distillation is weak, and not well flavoured; it is returned, therefore, into the still; what rises next is the richest and strongest product, and has the highest flavour of the essential oil of the wine it is prepared from; this is called *eau de vie première*, or brandy of the first quality.

As the process of distillation continues, the brandy becomes weaker and less flavoured; the last portions being set aside by the manufacturer, and re-distilled with fresh wine. The strength is tried by various methods: by the hydrometer, by observing the head, or by putting a small quantity on the head of the hot still to see if it will take fire. Another test of strength is by a drop of oil; when this sinks, if suffered to fall into the spirit, the latter is considered strong enough; this mode of testing is called *preuve de huile*, and indicates the strongest brandy that is drunk. When all the brandy of this strength has come over, they put it aside, and this operation they style *couper à la serpente*, which means to "stop the worm from running." The purest and most volatile essential oil rising with the first product, what comes afterward is not so agreeable, and of course the brandy, being both weaker and not of so fine a flavour, is considered as of an inferior kind, and is called *eau de vie second*, which is sometimes purified by a second distillation, but sold at a lower price.

It is said that the Cognac sent to England scarcely ever has the fine bouquet of the first distillation, because in this country the flavour and colour given by burned sugar is generally preferred. Hence, for exportation, the French re-distil the second brandy to make it stronger, and then flavour it for the English market. It is said that the flavour of the wine is so distinct in the best brandy, that persons in France accustomed to it can tell from the taste what wine it has been made from; and the manufacturers can at pleasure increase or diminish the quantity of aroma by a more rapid or slower distillation.

In distilling from very weak and poor wines, it is not customary to put aside "eau de vie première" in the first distillation, but to carry on the process till all the spirit is obtained, called *petite eau de vie*, and then to strengthen it by a second distillation. This the manufacturer who wishes to export finds it most profitable to do, in order to save the expense of the casks and carriage of a weaker brandy. For exportation they bring all to the strength of *trois-six*, which is in proportion to water as eight hundred and forty to a thousand. Brandy beyond "preuve de huile" is called *eau de vie double*; but it is seldom made above what they reckon twenty-two degrees of strength, because all above that pay nearly double duty. The best Cognac is twenty-one degrees and three quarters.

3730. *An inferior kind of brandy*, called *eau de vie de marc*, is also made from the *marc* of grapes, or the residue after the juice has been pressed out for making wine vinegar, which still retains enough of the grape juice to be readily brought into fermentation when properly arranged, and therefore is capable of yielding afterward a spirit by distillation; but the grape stones, and the resinous colouring matter of the fruit, together with the lees of wine and the scrapings of the casks, all put into the still, communicate a flavour which some consider bitterish and austere; others call it nutty, and relish it. But this inferior kind of brandy is twenty-five or thirty per cent. cheaper than the best, and is drunk only by the lower classes in France; this is sometimes preferred in England and in the north of Europe, where the burned flavour of sugar added to it, though actually a blemish, is by some considered as an indispensable quality.

The best Cognac brandy is distilled with a very gentle heat, not sufficient to raise too much of the essential oil of the wine; the palest white wines are chiefly used. Common French brandy, *eau de vie ordinaire*, is made from high-coloured white wine, or pale red wine: white wines give a softer brandy than red. Brandy made in France is often sophisticated by the manufacturers, who either put rectified malt or other spirit to the wine before distillation, by which the union is more complete than if added afterward.

A kind of brandy is also prepared in France by distilling a spirit from other materials; and after getting rid of the peculiar aroma, they add a portion of the best French brandy. Various sorts of agricultural produce are thus employed, as garden and orchard fruits, honey, molasses, corn, potatoes, beet root, or any other substances containing sugar. This in England is prevented by the excise.

3731. *The best French brandy* is naturally free from colour; it is clear and transparent as water, and in France it is often preserved so for use by being put into glass or stone bottles.

The general opinion in England, that a brownish yellow colour belongs essentially to brandy, is erroneous, and requires explanation. It had been remarked that all the fine foreign brandies that had an agreeable mellowness had also a yellow colour. The colour in this case had really nothing to do with their flavour; but the same age that was necessary to give them mellowness gave also a colour to the spirit, extracted from the wood of the casks in which it had been kept; hence the excellence of brandies was supposed to be connected with this tint. From this circumstance, great pains have been taken to colour brandies artificially to give them this appearance, which was thought to indicate age, until the English public has become so accustomed to it, that it is generally thought to be essential to the spirit. Various substances are accordingly used by French and English dealers for colouring brandies; as burned sugar, treacle, oak chips, logwood, saffron, and terra japonica. The first three are most employed. These methods may, however, be all considered properly as sophistications, though not deleterious.

3732. *Newly-distilled brandy* appears to contain a small quantity of uncombined acid. Chaptal observes that the thin or ill-fermented wines contain much *malic acid;* and that these, when distilled, yield a spirit which is of a bad quality, some of the acid having passed over in distillation at the same time; and such spirit has often an empyreumatic flavour. The richest and best brandies are freest from this acid, which disappears by age from combining intimately with the alcohol; hence the mellowness of old brandy. The union of the vegetable acids with the spirit in this natural way is so strong, that the compound bears the addition of water in any quantity, without causing a separation of the two constituents: genuine brandy, in which the fiery nature of the pure alcohol is softened through age by the combination of acid and the essential oil of wine with other matters, is considered to be less injurious to the animal fibre, and less hurtful to the constitution, than pure malt spirit. The malic acid in the brandy, in fact, forms with the alcohol a species of *malic ether.*

3733. *Spirit of wine was originally made by distilling it from brandy*, and continues still to be prepared in this manner in France, though with us it is procured from malt spirit.

3734. *It is important to be generally known*, that what is here called *British brandy is not, in fact, brandy*, this being the name for the spirit distilled from wine, as we have already stated. The *so-called* British brandy is said to be made chiefly from malt spirit, with the addition of mineral acids and various flavouring ingredients, the exact composition being kept secret. *It is merely an imitation of brandy, however nearly it may resemble it, and ought not to be called brandy*, if names are to be used for the purpose of distinguishing different substances.

3735. *Dr. Kitchener recommends travellers to carry with them*, in order to mix with water, as a beverage much safer than many others they may meet with, some brandy of the full strength, which will cost a little more than that commonly sold, which is usually ten per cent. below proof, and which, he observes, "crafty dealers put off as a fine, old, and mild spirit, though really only brandy and water, and attribute to age what they effect by aqueous adulteration; and so obtain, not only the profit arising from selling water at the price of brandy, but an extra sum for so doing, as a pretended remuneration for the immense loss of interest occasioned by having kept it till it is so exceedingly old and mild!"

3736. *A mixture of cider and rectified spirit* has been used for imitating French brandy, with the addition of wine lees. The cider and the spirit here will form *malic ether;* and such a mixture, if nothing else, or at least nothing of a deleterious kind, were added, would be less objectionable than some others, not being unwholesome; this has been recommended to be employed, where the price of French brandy is objectionable, in making certain liqueurs.

3737. *With respect to what are sometimes named brandy from potatoes*, and brandy from fruit of various kinds, it is scarcely necessary to mention, after what we have said, that such names are improper, since there can be *but one brandy*, and that is from the grape. What is distilled from other vegetables may be a strong spirit, but it cannot be brandy. It is true, as we have said, that the pure alcohol or spirit is the same, from whatever substance it is procured; but the spirits we have mentioned have not the flavour of true brandy, and differ from it in other respects. A close imitation can be effected only by the addition of other materials kept secret by the manufacturers, and therefore not to be trusted.

Among other adulterations of brandy, hot and pungent substances, such as pepper, ginger, capsicum, &c., are added for the purpose of making the brandy have the appearance of strength; they may be detected by evaporating a little of the suspected brandy nearly to dryness, when the acrid and burning taste will be sensibly increased, if such substances have been used.

Subsect. 2.—*Rum.*

3738. *Rum is prepared from materials which are the produce of the sugar-cane*, and is chiefly manufactured in the West Indies. These materials consist of molasses, or treacle, which is the uncrystallizable sirup that remains after the raw sugar has been formed. To this are added scummings of the hot cane juice from the boiling-house, which contains much of the aroma of the cane; or sometimes raw cane juice from canes expressed for the purpose; likewise lees called *Dunder*, consisting of the spent wash, or feculencies from a former distillation, and which serve the purpose of a ferment, like yeast in the brewing of beer; for though cane juice ferments of itself without yeast, yet this fermentation would be too slow.

These ingredients undergo the process of the vinous fermentation; and when the spirit is thus formed, it is separated by distillation. The flavour peculiar to this spirit, and which has rendered it famous in almost every part of the world, is derived from the essential oil of the sugar-cane, which is imparted during the fermentation, in consequence of the raw juice and fragments of the cane which are in the wash; a spirit may be distilled from sugar alone, fermented, called *sugar spirit*, but it is without the flavour of rum. Great quantities of rum are made in Jamaica, Barbadoes, Antigua, and other sugar islands. The following is the method of making it:

When the materials above mentioned are got together, they are diluted with water, and fermented in the usual manner. In Jamaica, the proportions are generally six gallons of molasses, thirty-six gallons of scummings of the sugar pans, fifty gallons of dunder from a former distillation, and eight gallons of water. If the rum is required of finer flavour, less of dunder is used, as that contains a good deal of empyreumatic matter. When this fermentation is completed, which is generally in about nine days, the fermented liquor or wash is put into a still, and the spirit, called *low wines*, is drawn off until it is no longer inflammable. To make this into rum of Jamaica proof, it undergoes a second distillation, in order to concentrate the spirit. Although the fermentation is, as we have stated, chiefly the vinous, yet so apt is the cane juice to become acid, that the acetous fermentation sets in slightly, whence it happens that the wash obtained has often a quantity of acetic acid as well as alcohol. As the heat of the distillation increases, the acid acts upon the alcohol, and distils over with the spirit, communicating to it a very disagreeable flavour and odour. Newly-distilled rum, therefore, has a peculiar bad taste, and is likewise extremely unwholesome, the acid, as well as the essential oil, being very deleterious to the nervous system; and the intoxicating power of new rum is much greater than might be expected from its proportion of alcohol. In some places, the leaves of different aromatic plants are thrown into the still to correct this flavour; but time alone, and suffering the rum to remain in the hogsheads long enough, can destroy the acidity or sharpness which it possesses when first distilled, and cause the essential oil to amalgamate with the liquor; accordingly, new spirit is stored in wooden vessels until the raw flavour is ameliorated; and hence old rum has a mildness and richness of flavour not possessed by new, and is always preferred. The wood itself appears to act a part in this process, for, if put into glass or earthen vessels, rum is said not to improve.

3739. *The best rum* is of a brown transparent colour; smooth, mellowed, oily taste; strong body and consistence: that of a clean, limpid colour, and hot, pungent taste, is either too new, or has been mixed with other spirits. *Jamaica rum* is the first in point of quality; the *Leeward Island rum* being always inferior to it in point of flavour, strength, and value: the price of the latter is usually twenty per cent. below that of the former, which occasions the Jamaica rum, it is said, to be sometimes adulterated by the latter.

3740. *Pineapple Rum.*—It is customary in some of the West India islands to put sliced pineapples in puncheons of rum, which give the spirit the peculiar flavour of that fruit. *Double-distilled rum* is rum rectified to a strength approaching to that of spirit of wine, which is convenient for carriage.

3741. *Rum is, like all other spirits, not unfrequently* "doctored," as it is called. Bad rum is made to imitate good by the addition of various ingredients. Those additions are kept secret, but are mentioned in books devoted to the purpose of exposing such frauds; as "Shannon on Brewing and Distilling," "Wine and Spirit Adulterators Unmasked," &c.

3742. *In France they make a sort of rum from the molasses* which remains after the making of beet-root sugar; but the spirit from molasses alone has not the proper flavour of rum, proving that this flavour is derived from the essential oil of the cane existing in the cane juice, and which is dissipated by the heat employed in procuring molasses. It is said that a good deal of spirit is made in this country from molasses of cane sugar by the distillers for purposes of adulteration.

SUBSECT. 3.—*Corn, or Malt Spirit.*

3743. *Various kinds of ardent spirits are produced from grain in different parts of the world;* but we propose to consider here only such as are made in this country.

When ardent spirit is prepared from grain, the first part of the process is nearly the same as in brewing: the malt is mashed and fermented for the purpose of producing the alcohol, only it is not hopped; the produce being, in fact, a kind of unhopped ale, and from this the spirit is to be separated by distillation.

3744. *In Britain the distillers do not brew entirely from pure malt*; they use chiefly raw grain, which saves the expense of malting. The proportion of malt usually varies from as little as one tenth part of the raw grain to one half of malt. The act of Parliament provides for the using of malt or raw grain, and leaves it at the discretion of the distiller to use either, on giving proper notice of his intention to that effect. But every distiller is obliged to use at least one fourth of malt, or pay duty to that amount. This mixture is ground; then the grist is infused with water at a heat of about 145°, which is considerably lower than that of the water used by the brewer, as there is more risk of setting with unmalted grain; and, for the same reason, more agitation is used in mashing.

3745. *This first process, however, differs from brewing in some important particulars:* in the latter, it is not desirable to carry the fermentation as far as possible, for the reasons which we stated when treating on brewing; but in distilling spirits, they endeavour to carry the fermentation to the utmost limit, and decompose the whole of the saccharine matter, in order to obtain all the spirit they can, the quantity of this being just in proportion to the decomposition.

3746. *The wort is drawn off and cooled in the usual way,* and fresh water poured on to exhaust the grain. The wort thus formed is not so transparent as that from malt, but its taste is nearly as sweet. It would appear, therefore, that the starch in the raw grain undergoes a certain change during the mashing, and is brought towards the state of saccharine matter as if it had been malted; a curious fact which was first discovered by the distillers. The wort is then put into the fermenting tun at a low temperature, varying from 55° to 70°, according to the quantity, the season, the goodness of the yeast, and the skill of the distiller. Here it is mixed successively with considerable portions of the best yeast that can be procured from a previous fermentation of the same kind, and the fermentation is urged as far as it can be made to go without danger of acetification. This process generally lasts about ten days, and the temperature rises usually to between 90° and 100°, and sometimes higher.

3747. *By this fermentation the saccharine matter is converted into alcohol,* and the liquor which is produced is what the distillers call *wash.* This wash is now put into the still, and the produce of the distillation is a very weak and foul spirit, called *singlings*, or, by some, *low wines*, or spirits of the first extraction. These low wines are re-distilled, or, as it is called, *doubled;* what comes over first is a very fiery spirit, tolerably pure, called *first shot;* the part which comes afterward is called *malt spirit*, which is slightly impregnated with the essential oil of the barley, and is received till its gravity diminishes to a certain degree, and it begins to acquire an ill taste and smell. What comes over afterward, and which is too strong of the essential oil of the grain, is called *faints;* and this is mixed with low wines, and rectified or submitted to a second distillation. The lower the heat, the purer will be the spirit that comes over, and the more certainly will the fetid essential oil be left behind in the water. The grains and the liquor which remain in the still after the singlings, or low wines, have been drawn off are called *still bottoms*, and are used to feed pigs, which, on that account, are often kept by distillers.

3748. *In distilling, it is an object of economy to ascertain what substances will afford the most spirit in proportion to its price.* Barley appears to produce less spirit than wheat; and if three parts of raw wheat be mixed with one of malted barley, the produce is said to be particularly fine. This is the practice of the distillers in Holland in making the best Geneva; but in England they are prohibited from using more than one part of wheat to two of other grain. Rye, however, affords more spirit than wheat. In Scotland it is the practice to use one part of malted to from four to nine parts of unmalted grain.

It is reckoned that it requires a hundred gallons of malt wash to produce twenty of spirit that contains sixty parts of alcohol and fifty of water.

3749. *The well-known whiskey is distilled from a fermented liquor, or wash, made from malt,* or malt and raw grain, either barley or oats. Wheat is sometimes used, but its high price in general limits its distillation. The peculiar flavour of Scotch and Irish whiskey has generally been supposed to be owing to the malt having been dried by turf: this does not, however, appear to be the case, since Mr. Donovan states that he was informed by an Irish distiller of the famous "Potteen whiskey," that the flavour was the same, whether the malt was made with turf or coal.

There can be little doubt that this flavour is produced by essential oil produced during distillation, which combines with the alcohol in making the wash, and which rises with the spirit in distilling with a low heat. This essential oil was obtained in small quantities, and mentioned long ago by Dr. Thomson, of Glasgow, and lately a method has been found out of procuring it by an easy process; it is extremely pungent, and a small drop is sufficient to impregnate a large quantity of pure spirit with the precise odour and flavour of whiskey. The production of this essential oil is completely prevented in the fermentation of beer by the presence of the volatile oil of the hops.

3750. *To make whiskey,* a wash is made by fermenting the materials mentioned above; this is distilled, and the spirit first obtained, or the low wines, are weak. They are redistilled, and the spirit so procured is whiskey, the strength of which is then about twenty-five per cent. above proof. Several places in Scotland and Ireland have been long celebrated for their superiority in the manufacture of this potent liquor. Dr. Thomson observes (*Sup. Encyc. Brit.*) that Lowland Scotch distillers use porter yeast in the fermenting of their wash, which gives a bad flavour to their whiskey; and that one cause of the superiority of the Highland whiskey (which has been termed "mountain dew") is, that the distillers there, particularly the smugglers, have not the means of procuring porter yeast from London. In Scotland and Ireland, much of the spirit produced by the distiller is consumed in the state of whiskey, and there are but comparatively few rectifiers in those countries; but much also is sent to London to be made into gin.

SUBSECT. 4.—*Spirit from various Vegetable Substances.*

3751. *Spirit from Potatoes.*—In some parts of the Continent a great deal of spirit is distilled from potatoes: these form an excellent material for this purpose, as they contain about five per cent. of starch. There are two methods of performing this: one is to convert potato starch into sugar, and then to ferment the sugar, and distil from the fermented liquor; the other process is to procure the spirit from the potatoes without making starch.

3752. For the first method, the following process has been employed: 75 gallons of water are put into a fermenting vat lined with lead, and capable of holding 250 gallons. The water is heated by means of steam to 176°. In another vessel, also lined with lead, 3 cwt. of potato starch, 6 cwt. of water, and 6 lbs. of oil of vitriol are mixed, and the whole poured into the first vessel, the heat being carefully maintained. In about six hours the starch will be converted into sugar. To get rid of the acid, 20 lbs. of whiting are added to neutralize it; the saccharine liquor is then drawn off, fermented with yeast, and the spirit distilled from it.

3753. For the second method, the potatoes are steamed, bruised into the state of pulp, and thrown into a tub with water of the temperature of 63°, in the proportion of 416 lbs. of water to every 100 lbs. of potatoes; the whole must then be suffered to ferment. While this is going on, 31 lbs. of malt in a state of fermentation are added, and the whole fermented together.

As potato juice contains a small quantity of tartaric acid, a little potash made caustic must be added to neutralize the acid; and it also serves to dissolve the albuminous matter that had been coagulated by the heat, and thus give complete fluidity to the mass. About half a pound of potash is sufficient for every 100 lbs. of potatoes. The fermentation finishes in about from 48 to 60 hours, when a spirituous odour will be perceived.

This fermented mass is now passed through a sieve to separate the pulp of the potatoes, and the liquor is put into the still. The spirit afforded by distillation will be in the proportion of 8 French pints of spirit for every 100 lbs. of potatoes: and the strength of the spirit will be such that it will contain 30 per cent. of pure alcohol. It is found that 3½ bushels of potatoes afford as much spirit as one bushel of malt; or 38 cwt. of potatoes and 200 gallons of malt will yield about 225 gallons of spirit.

The peculiar taste of potato spirit is removed by rectifying it with chloride of lime, about an ounce to each ten gallons of spirit; but roots and carrots mixed with the potatoes improve the flavour of the spirit. Some add aniseed or other flavouring ingredients. As potatoes pass readily into the acetous fermentation, the process requires to be conducted with great care.

3754. A brewery and distillery are common accompaniments of farming establishments in Germany and Norway; the farmers there produce spirit from potatoes as well as from barley, for their own use and that of their servants and labourers. We confess, we do not wish to see this example followed in this country, conceiving spirits less wholesome than beer. In France there are large manufactories for making sugar from potatoes, and for making spirit from the sugar. It must be observed that our laws do not permit the distillation of spirit from potatoes.

3755. *Birch Spirit.*—The sap of several trees contains sufficient saccharine matter to yield a spirit. The Swedes make a kind of strong spirit from the juice of the birch, by fermentation and distillation; and the ash is employed for the same purpose in northern countries.

3756. *Peach Brandy.*—A great deal of this *so-called* spirit is made in America, both South and North; and likewise in Persia, where this fruit grows in abundance. The process is the same as that employed in making spirit from cherries.

3757. *Cider Spirit.*—This is occasionally distilled in Devonshire from the lees of cider; but the flavour of the spirit is not to be commended. It may, however, be much improved by careful rectification, and has been made to imitate brandy by means of some additions.

3758. *Spirit from beet root* has been made in the following manner: Procure a quantity of the same beet roots that is employed for the manufacture of sugar; wash them well, and boil them in steam; mash them in two thirds of their weight of boiling water, and add a thirtieth of their weight of ground malt. Mix this well together, and leave the whole in a covered vessel for three hours; strain it through a wire sieve having the meshes one third of an inch square. When the temperature has fallen to 77°, add the proper quantity of yeast, and ferment in a covered tun. The fermentation will be finished in five or six days, and the wash is then to be put into a still and the spirit drawn off. A hundred lbs. of beet root will afford ten or twelve lbs. of proof spirits.

3759. *Spirits can be made from various other vegetable substances*, as carrots, gooseberries, the service berry, horse-chestnuts, even some kinds of sweet grass, any vegetables, in fact, which contain sugar; but they are not important enough to deserve particular description.

SUBSECT. 5.—*Arrack.*

3760. *Arrack is the East Indian name for all ardent spirits*, and it is made there from various materials. One kind of arrack is distilled from rice; another is made from the juice of various species of palm; a third from both these mixed; and another from molasses and mowah, a kind of sweet berry.

3761. *In making arrack from rice*, the grain called *ketan*, or glutinous rice, is used by the natives; it is boiled, and having a ferment added, called *rasi*, it is exposed in open tubs till fermentation takes place, when the liquor is put into earthen vessels, and kept buried in the earth for some months to check the fermentation. Large quantities of arrack are made in Batavia, where molasses and toddy are mixed with the rice before it is fermented; after fermentation the liquor is distilled, and the spirit thus produced is the best arrack.

3762. *Arrack from the juice of the palm* is made in the following manner: The species of palm from which the juice is obtained are the *Borassus flabelliformis*, *Cocos nucifera*, or cocoanut-tree, or the date-tree. The juice, when fresh drawn from an incision made in the stem, is a sweet, cooling, and wholesome beverage, called *toddy*, and by the natives *tari*. It contains much sugar, which, when separated by boiling, is called *jaggery*. The sap in its natural state is brought to market in large quantities, but it becomes sour in three or four days. When fermented into an intoxicating liquor, it affords one of the best kinds of Indian arrack by distillation. The trees from which the toddy is obtained are not suffered to bear any fruit. There are two ways of obtaining the toddy. One method is this: The person provides himself with a sufficient number of small earthen pots, resembling in form our glass bottles; he fastens several of these to his girdle, or to a belt across his shoulders, and climbs up the tall trunk of the cocoa-tree, or other palm. Having reached the top of the tree, where the large leaves form a great bunch, he cuts off with a knife the small buds or monthly shoots from which the fruit would be produced, and applies immediately to the wound one of his bottles, which he fastens on with a string. In this manner he proceeds till he has fixed the whole number of bottles in his girdle, which serve to receive the juice that flows out. This operation is generally performed in the evening, a greater quantity of juice flowing from the tree in the night than during the day. Another method is to make a perforation in the trunk of the tree, which is kept plugged up, unless when the gatherers are about to collect the sap. When put into vessels and kept out of the sun, the toddy undergoes the vinous fermentation, and is fit for distilling into arrack; but if it be exposed to the sun, it passes into the acetous fermentation, and is changed into vinegar.

3763. *The best arrack is the Batavian*, called *knap*; next is the Madras: the Goa and Columbo are inferior. The common Pariah arrack is often made from jaggery, rendered more intoxicating by hemp leaves, the juice of stramonium, and poppy heads, and is dangerous to Europeans. The consumption of arrack in India is very considerable, although the Hindoos, as well as the Mohammedans, are forbidden by their religions to use ardent spirits. Besides arrack, the natives of India distil intoxicating liquors from various plants; one made from the date-palm is of great antiquity: Herodotus mentions it as one of the principal articles of commerce in Babylonia.

A very bad imitation of arrack, made out of rum, is recommended by Dr. Kitchener, in his "Cook's Oracle" (p. 497), under the name of "*mock arrack*." "Dissolve two scruples of flowers of benjamin (benzoic acid) in a quart of good rum, and it will immediately impart to it the inviting fragrance of '*Vauxhall nectar*.'" Whether "Vauxhall nectar" was so composed, we have no means of determining.

SUBSECT. 6.—*Proof Spirit.*

The mode of judging of the strength of spirituous liquors by the taste is not always to be depended upon, as a false appearance of strength is sometimes given to a weak liquor by the infusion of acrid and pungent substances.

3764. *By the excise laws at present existing in the British islands, a duty is paid on spirituous liquors*, such as brandy, rum, arrack, gin, whiskey, &c., in proportion to their strength; *and the strength of these liquors depends upon the quantity of alcohol which they contain.*

Pure spirit, or alcohol, is considerably lighter than water; a mixture of alcohol and water will, of course, be lighter than water alone; from which it is evident that the more alcohol any liquor contains the lighter it must be. Hence, the quantity of alcohol in a mixture of it with water, or, in other words, its strength, may be determined by its comparative weight or specific gravity. See Alcohol in "Fermentation," Book VIII., Chap. II.

3765. *In order to compare the degrees of strength of various kinds of spirit*, the excise has established one degree of strength as a legal standard, and this they call *proof*, or *proof spirit*. "This liquor (not being spirit sweetened, or having any ingredient dissolved in it to defeat the strength thereof), at the temperature of 51° Fahrenheit, weighs exactly 12-13ths of an equal measure of distilled water." Its specific gravity is ·930.

3766. *The strength of spirituous liquors, when greater or less than this*, is said to be *above* or *below proof*; and, in the latter case, is estimated by the quantity of water which would be necessary to bring the spirit up to the weight of proof.

3767. *As it is necessary to have an accurate mode of ascertaining the strength of spirits*, particularly in case of purchasing a large quantity, various means have been resorted to to determine this. The most accurate mode, and the only one to be depended upon, is by the instrument called the *hydrometer*, which ascertains the specific gravity of the liquid.

3768. *The hydrometer* is a hollow ball with weights fixed to a stem, which sinks deepest in the lightest fluid; therefore the strength of the liquor may be determined by the depth to which the stem sinks. A mark is fixed on the stem for the depth to which it will sink in proof spirits; all spirits in which it sinks deeper are *over* proof, and those in which it sinks less are *below* proof; by the divisions in the stem, together with the weights employed, the exact degree of strength may be ascertained. This is the method prescribed by the excise laws for trying the strength of liquors.

There are several hydrometers, varying somewhat in form; but *Sykes's hydrometer* is that used by the excise. This method of ascertaining the strength of liquors requires some precautions in using the instrument. The difference of temperature materially affects the specific gravity of the fluids; therefore a thermometer is also employed to discover this at the time the hydrometer is used. But, to avoid the complicated calculations that would be necessary for this and other allowances to be made, tables are constructed, which renders the business very simple to the excise officer. He has only to put his hydrometer into the liquor, observe certain marks, and also try the temperature with his thermometer; then from these observations, by means of rules laid down for him, and his printed tables, he readily finds the strength of the spirit. The convenience and utility of this mode are incalculable; and to illustrate it, Dr. Arnott relates an interesting anecdote. "A shopkeeper in China sold to the purser of a ship a quantity of distilled spirit according to a sample shown; but not standing in awe of conscience, he afterward, in the privity of his storehouse, added a certain quantity of water to each cask. The spirit having been delivered on board, and tried by the hydrometer, was discovered to be wanting in strength. When the vender was charged with the intended fraud, he at first denied it, for he knew of no human means which could have made the discovery; but on the exact quantity of water which had been mixed being specified, a superstitious dread seized him, and having confessed his roguery, he made ample amends. On the instrument of his detection being afterward shown to him, he offered any price for what he foresaw might be turned to great account in his trade."

3769. *In purchasing large quantities of spirits of any kind*, the hydrometer should always be employed; but other methods less scientific have been, and still are resorted to on common occasions for trying the strength, when no hydrometer is at hand. The most usual is what is called the *Bead proof*, the mode of examination by which is as follows: Take a long vial, fill it half way with the common malt spirit, and give it a smart stroke by its bottom against the palm of the hand; there will then appear on the surface a chaplet or crown of bubbles, which will go off again in a peculiar manner; that is, first remaining a while, and then going off by degrees, without breaking into smaller bubbles, or swelling into larger. If the bubbles raised in any spirits are larger than those on proof spirits, and go off more suddenly, then the liquid is concluded to be *above* proof; if the bubbles are smaller than those on proof spirit, and go off quicker or fainter, the liquid is thought to be *below* proof. This test is very liable to be fallacious, though experienced dealers depend much upon it; but some of those who sell spirits know how to add certain substances to what is below proof, so as to show the same bead as that which is full proof; and as an instance how daringly such impositions are practised, we find, in a well-known work on distilling, distinct and express instructions how to deceive the purchaser.

3770. *The original mode of determining the strength of spirits*, whence the term "proof" was derived, was by pouring some of the spirit upon gunpowder, and setting fire to it. If, at the end of the combustion, the flame of the spirit fired the gunpowder, it was said to be proof; on the contrary, if the gunpowder did not take fire through the spirit having too much water, the spirit was considered as below proof. This method is very inaccurate.

3771. *For ordinary purposes, the relative strength of spirits may be known* by weighing the sample to be tried in a vial capable of holding exactly 500 grains of water. An equal bulk of rectified spirits weighs 418 grains, and of proof spirit, 465; hence the number of grains above or below these sums will indicate the relative strength of the spirit. Rectified spirits have a specific gravity of ·835, and proof spirit of ·930; so that in strength, nine of the former are nearly equal to ten of the latter. French brandy is about the same strength as proof spirit; Scotch whiskey has 54·32 of water; Irish whiskey about 53·4; rum, 53·68; gin, 51·6.

3772. *The most exact of all methods of determining the strength of spirits* is by distillation; rectifying it up to alcohol, and ascertaining how much alcohol there is in a given quantity; but though liable to no error, this is too tedious to come into common use.

Proof spirit contains about equal parts water and rectified spirit; rectified spirit of moderate strength has generally about 25 per cent. of water; and *alcohol* is all spirit.

Proof spirit cannot, like rectified spirit or spirits of wine, be used for burning in lamps, nor for dissolving resins, nor for making varnish, and many tinctures, not being strong enough.

3773. *When spirit is said to be one to three over proof*, it is meant that one gallon of water added to three gallons of spirits will reduce it to proof; on the contrary, one in three under proof signifies that in three gallons of that spirit there is contained one gallon of water, and the remaining two gallons are proof spirits.

Subsect. 7.—*Rectification of Spirits.*

3774. We have shown that the object of the distiller is to procure from fermented liquors all the pure spirit which they contain; and we have stated that all spirits are the produce of fermentation only, and that when rendered perfectly pure they are of the same nature, from whatever source they have been derived, whether from wine, malt, sugar, potatoes, &c. But they are never obtained in a pure state in the first distillation; independently of the water with which they are diluted, they contain other impurities. Brandy made from wine has a peculiar essential oil, derived from the grape, with some acid, &c.; rum is impregnated with another essential oil from the sugar-cane, together with other impurities; malt liquor has the essential oil of barley; in short, every spirit when first procured will have some impregnation of an essential oil, and some other substances in small quantity, but sufficient to communicate a peculiar flavour; and this, independently of the strength, constitutes the difference between one spirituous liquor and another.

3775. *The business of the rectifier* is to deprive the spirit of the water, essential oil, and other impurities, which process is called *rectification.* It is extremely desirable to have a pure flavourless spirit, for various purposes; as, for instance, in the case of making perfumed essences; for if the spirit in which the odoriferous oil is dissolved has in itself any peculiar odour, the perfume will be less perfect. It is also necessary to have a spirit as free as possible from peculiar flavour, when, as in the case of compound spirits, such as gin and cordials, certain flavours are to be imparted: hence rectifiers have had recourse to various expedients, and a great deal of their knowledge is kept secret.

It is very important that in the first distillation, particularly from malt or barley, the spirit should be drawn with a gentle fire, by which means great part of the essential oil will be prevented from rising and mixing with the spirit; and experience proves that it is much easier to keep asunder substances than to separate them when once they are mixed. But as it is almost impossible, with the greatest care, to draw over a spirit without its being at first impregnated more or less with essential oil, it is necessary to have some method of separating these: the best methods for effecting this are re-distillation and filtration.

3776. *Spirits drawn from wine*, such as French brandy, may in a great measure be purified or rectified by simple distillation in tall vessels or alembics, and gently distilled in a *balneum mariæ*, or water bath; the pure spirituous part rising first, a large proportion both of the oil and phlegm remains behind in the still. If French brandy be thus distilled to one half, the spirit obtained proves tolerably pure; and it was in this manner pure spirit was first procured, called from thence spirit of wine; this method is still employed in France. But wine and brandy being articles too dear in this country, recourse is usually had to the common spirit from malt or molasses, termed in its first state *raw spirit*, which is rectified for spirit of wine.

3777. *To separate the essential oil with which the raw spirit abounds*, it is mixed with an equal quantity of spring water, and is put into a still, and distilled with a very gentle heat. The first product of the distillation is the strongest and purest, and when it has come over, to the amount of one fourth of the whole contents of the still, it forms the rectified spirit. If the distillation be continued, the spirit continues to come over, but weaker and weaker, till at length it is so watery as not to be inflammable. What remains in the still is water, the colouring ingredients, with any accidental impurities; the water is generally turbid, and very nauseous in smell. When the ardent spirits which have been employed contain much essential oil, the distillation requires to be repeated before it can be purified from all ill flavour; and as this process is tedious, to expedite it, the distillers frequently mix with the impure spirit some potash, lime, or other alkaline substance. When potash is used, the spirit has a urinous taste; to free it from which, it is again distilled with the addition of a little alum and charcoal, the acid of the former attracting the small portion of potash which the spirit held in solution. Malt spirit, when properly rectified, yields as pure and as strong a rectified spirit as brandy.

3778. *The raw spirit is sold to the rectifier in the state of proof spirit*, and when it is converted into rectified spirit, it is sold as spirit of wine, or it is made into compounds commonly called *liqueurs* or *cordials*, by being distilled with certain herbs and other ingredients.

3779. *Rectified spirit, or common spirit of wine*, being spirit freed from the essential oils above mentioned, is in the highest state of concentration in which it can be easily prepared in the large way for the purpose of trade.

3780. *Properties of Spirit of Wine.*—It has a fragrant odour, a hot, highly pungent taste. It is colourless; always fluid; cannot be congealed at any known degree of cold; evaporates speedily at the ordinary temperature of the atmosphere; boils at 163°, and is extremely inflammable, burning with a blue lambent flame, without any sensible smoke. Like alcohol, it combines with water in every proportion; it is capable of dissolving many saline bodies, and is the proper solvent of the great number of the proximate principles of vegetables, particularly resins. Expressed oils, which swim on water, will sink in rectified spirit. It is composed of 85 parts of pure alcohol and 15 of water in 100 parts, when its specific gravity is ·835 at a temperature of 60°. It is a powerful stimulant, but is never taken into the stomach in its undiluted state. Diluted to the degree of proof spirit, it is still too strong for internal use.

Subsect. 8.—*Compound Spirituous Liquors.*

3781. In treating of the business of the rectifier, we have hitherto confined ourselves to the art of depriving distilled spirits of the essential oils and other matters with which they are contaminated, in order to produce a pure spirit approaching nearly to the nature of alcohol.

3782. *We have now to treat of those compounds which are produced by adding to pure spirit certain ingredients for the purpose of giving to it agreeable flavours*, or for other uses. Most of these are now generally manufactured in the large way by the rectifier; but their nature and composition are subjects of no small importance to the health of the public, as well as their gratification; and it is on this account chiefly that we consider it deserving attention, since we believe many of those most interested in them are not well-informed of many facts that should be known.

3783. *Impregnating spirits with flavouring substances is a practice of old times*, and was frequently done through the idea of giving them a medicinal quality, real or supposed; hence the name of *cordials*, yet so frequent in the shops, are insidious terms that serve too often as an excuse for dram-drinking, although it cannot be denied that some of them, judiciously employed on certain occasions, have beneficial effects. One of the most ancient of these appears to be *usquebach*, or *aqua vitæ;* and *Geneva*, both Dutch and English, belongs to this class, as well as the vast number of the more elegant foreign compounds designated *liqueurs.*

3784. *Of compound spirits some are made by our rectifiers, and others are imported from the Continent;* but as it has been always considered a branch of domestic economy to prepare a few of them at home, we shall describe their composition, and the manner of producing them, either to lessen their expense, or for the sake of showing what ingredients they contain.

3785. *In all these operations, it is an object with the rectifier*, or whoever attempts to form these compounds, first to obtain as pure a spirit as possible, that the natural flavour of the raw spirit may not interfere with the flavours to be communicated. It is not our object to enter into the details of the various processes of the manufacturer who works on the great scale, any farther than to give a general idea of the subject; but our directions for those processes which may be carried on at home will be more minute, referring the reader, at the same time, to Book XX., "On the Still Room," for a variety of information applicable to this, as well as to some other subjects of domestic economy.

3786. Some compound spirits are prepared by putting the spirit, together with the flavouring ingredients, into the still, applying heat, and drawing off the spirit impregnated. Another class is produced by simply infusing the flavouring materials in the spirit without distillation. The latter are sometimes termed *ratafias*, a name derived from France.

Subsect. 9.—*Geneva and Gin.*

3787. The term *Geneva* and *gin*, the name of a well-known spirit, is derived from *genèvre*, the French for juniper-berry. Shaw, in his "Essay on Distilling," informs us that originally it was a custom to add to the fermenting worts for distilling spirits some aromatic ingredients to take off the bad flavour, and give a pungent taste to the liquor. Among other things, juniper berries were tried by Sylvius, a professor of Leyden, who lived in the seventeenth century; and it was found not only that they gave a very agreeable flavour, but likewise communicated valuable medicinal qualities. This liquor was, accordingly, first sold as a diuretic in the apothecaries' shops; but as it was drunk with avidity, it soon became an article of trade, and received the name of the plant which gave the peculiar flavour.

3788. The original Geneva was made in Holland by grinding berries with the malt before fermentation, and fermenting the whole together, by which the spirit was flavoured with the juniper from the beginning, a method preferable to any other.

3789. *The English Geneva was an imitation of that made in Holland*, and, like it, was rectified from juniper; but it having been found out that the oil of juniper and the oil of turpentine were very like each other in flavour, the last being by much the cheapest, our distillers omitted the greatest part of the juniper, using chiefly turpentine. English gin is, therefore, only raw corn spirit and oil of turpentine distilled together by the rectifiers; occasionally some juniper is added, together with various other ingredients.

3790. *Hollands*, or *Dutch Geneva of the best quality*, is made at Schiedam, but it is likewise made very good at Delft, Rotterdam, Dordrecht, and Weesoppe.

3791 The usual manner of manufacturing it is thus described: "A quantity of flour of rye, coarsely ground, is mixed with a third or fourth part of barley malt, proportioned to the size of the tub in which the vinous fermentation is to be effected. This they mix with cold water, and then stir it with the hand, to prevent the flour from gathering into lumps, and to facilitate its dissolution. When this point is attained, water is added of the heat of the human blood. The whole is well stirred, after which the ferment or yeast is mixed with the wort, being previously diluted with a little of the liquor. The fermentation generally begins six hours afterward: if it commence earlier, there is reason to apprehend it will be too strong, and means are employed to check it If the fermentation be well conducted, it generally terminates on the third day, when the liquor grows transparent, acquires an acrid taste, hot and biting on the tongue. The wash is then well stirred, and the mash with all the corn is put into the still, and then commences the first distillation, which is conducted very slowly, that being a matter of the utmost importance. This liquor is then rectified over juniper berries once or twice, according to the sort of spirit which it is intended to produce. For common use, one rectification is deemed sufficient, though the spirit is not considered so agreeable as that which has undergone several rectifications, and which is called double Geneva. Some distillers mix the juniper berries with the wort, and ferment them together; but in that case they only draw a spirit from it for the use of the interior, or for exportation to England.

An inferior kind of Geneva is made at Weesoppe, with a less proportion of berries, some fennel seeds, and Strasburg turpentine.

3792. *The plant which produces the juniper berries* (*Juniperis communis*) belongs to the Coniferæ, and grows abundantly in most parts of Europe. It flourishes in almost any soil; granite rocks, sandy heaths, and fertile plains appear to suit equally this plant. The fruit or berries brought from Italy are preferred to those from Germany. They are abundant and cheap in Holland, being procured from Cologne and Coblentz, and are likewise indigenous in Britain. The whole of the plant yields the oil, the extremities of the shoots as well as the fruit, but that produced by the former is more nauseous, and therefore little employed.

The fruit or berries are round, of a blackish purple colour, and contain an essential oil in their minute vesicles, requiring to be bruised that the oil may be freed in distillation. This oil, when obtained separately, is of a greenish-yellow colour, and has an odour moderately strong, not disagreeable, and resembling that of turpentine. The taste of the berries when chewed is warm, sweetish, and pungent, followed by bitterness. The oil is soluble in alcohol, and may be obtained on distillation with water. The flavour is superior to that of turpentine, but their greater price, increased by a duty of 11*s*. 1*d*. per cwt., is no doubt the principal reason why they are so much less used here than turpentine for gin. Notwithstanding this, it is said that from 600 to 800 tons are annually imported.

3793. *Although in Holland the quantity of grain that is grown is inadequate to the consumption of its inhabitants*, yet there are few countries better supplied with that necessary of life. From Russia, Poland, Elbing, Koningsburg, and Flanders are drawn those immense resources which enable the Dutch to distil to so great an extent; but Dr. Render, in his "Tour through Germany," informs us that a great deal of the spirituous liquor imported as Hollands is actually manufactured in Germany. In most of the wine districts on the Rhine, the Germans make a liquor, called *troster*, by fermenting the skins of grapes that have been pressed with ground barley or rye; this liquor is considered very wholesome, and immense quantities of it are sold to the Dutch, who use it in distilling their Geneva. All over Germany there are not only many large distilleries, but many of the farmers distil spirits for themselves, as they are only obliged to pay two florins, about 4*s*. 6*d*., for a license. In producing spirits, they use not only grain, but plums and fruits of various kinds, and likewise potatoes. The principal part of this is sold at the fairs in casks.

3794. *The best English gin* is said to be made thus: Into the still are put ten gallons of proof spirits, together with three pounds of juniper berries, and water four gallons; the spirit is drawn off by a gentle fire till the faints begin to rise, and it is lowered with water as much as is necessary. Distillers call the gin *royal* when it is the strength of proof.

3795. *The following is said to be the mode in which the common gin is usually prepared in England:* Ordinary malt spirits are put into a still with the other ingredients in the following proportion: five gallons of spirit, one ounce oil of turpentine, half a pound of juniper berries, two ounces of sweet fennel and caraway seeds, and a good handful of bay salt. This is distilled off till the faints begin to rise. As much water is added to the product as is found necessary. They reckon that ten gallons of spirit will make thus fifteen gallons of common gin; and some say that turpentine alone, and not juniper, is used. The turpentine, however, is not a deleterious ingredient. Dr. A. T. Thomson observes, in his "Materia Medica," "if the spirit were good, the English gin is a better diuretic than Hollands, inasmuch as the oil of turpentine is a superior diuretic to the juniper."

3796. *That British gin is often adulterated is notorious;* the late examinations before a committee of the House of Commons have opened the eyes of the public to the dreadful extent to which the consumption of this pernicious article has reached, and some of the fraudulent practices employed in adulterating it; but it is not to be expected that the whole of the deleterious substances used should ever be completely discovered. *Lowering* the gin usually retailed with water, and sweetening with sugar, though an adulteration and fraud almost universally practised, is the least to be regretted. The latter substance may be easily detected by evaporating a quantity of the liquor in a silver spoon over a candle to dryness; the sugar will be rendered obvious, in the form of a gum-like substance, when the spirit is volatilized.

Subsect. 10.—*Usquebach.*

3797. *Irish usquebach was originally a liqueur*, a compound spirit made with spices. It was called *aqua vitæ*, and was supposed to have the power of arresting many diseases, and prolonging health and life. Among other receipts for making it, the following is one:

"Take of nutmegs, cloves, and cinnamon, of each, two ounces; of the seeds of anise, caraway, and coriander, each four ounces; liquorice sliced, half a pound; bruise the seeds and spices, and put them, together with the liquorice, into a still with eleven gallons of proof spirits, and two gallons of water. Distil with a pretty fresh fire till the *faints* begin to rise. As soon as the liquor comes over, fix some saffron to the end of the worm, that the liquor may pass through it and extract its tincture. Soften the whole with sugar"

The term aqua vitæ has been often applied to whiskey, and also to English gin. Spirituous liquors appear to have been much drunk in Ireland at a very early period; and in the reign of Henry VIII. it was decreed that "there be but one maker of aqua vitæ in every borough upon pain of 6*s*. 8*d*."

3798. *Another receipt for usquebach* directs that the following ingredients should be digested in five gallons of French brandy for a fortnight, viz.: nutmegs, cassia-cinnamon, angelica root, hay saffron, rhubarb, of each one ounce; mace, cloves, lesser cardamom seeds, of each two drachms; liquorice root, three ounces; coriander seeds, aniseeds, tumeric root, caraway seeds, of each one ounce.

3799. *Meg Dod's Usquebach.*—To two quarts of the best brandy or whiskey without a smoky or peculiar taste, put a pound of stoned raisins, half an ounce of nutmeg, quarter of an ounce of cloves, the same quantity of cardamoms, all bruised in a mortar; the rind of a Seville orange rubbed off on lumps of sugar, a little tincture of saffron, and half a pound of brown candy-sugar. Shake the infusion every day for a fortnight, and filter it for use. *Obs.*, not a drop of water must be put to this cordial. It is sometimes tinged of a fine green with the juice of spinach, instead of the saffron tint, from which it probably takes the name of usquebach, or yellow water.

SUBSECT. 11.—*Ratafias.*

3800. *Ratafias are liqueurs prepared by infusing the juices and kernels of fruits in strong spirit with sugar*, and are, therefore, to be considered as *tinctures sweetened.* Though the liqueurs, by distillation, would be difficult to prepare in a private family, ratafias are easily made. For this purpose, it is very important that the spirit should be of sufficient strength, since a strong spirit is enabled to extract certain vegetable substances more effectually than a weaker one. Genuine French brandy is usually recommended; but as this is expensive, rectified spirit may be advantageously employed. The chief use of ratafia is for imparting an agreeable flavour to puddings, pies, and other dishes.

3801. *Ratafia of Cherries, or Red Ratafia.*—Take two quarts of rectified spirits of wine; add to it two drachms of beaten cinnamon, one drachm of bruised cloves, and an ounce of coriander seeds, also bruised. Let them stand together well covered for a week; then press, from equal quantities of morello and black-heart cherries, twelve pints of juice, to which add three pounds of powdered loaf-sugar, and stir it till it is dissolved. Mix these with the spirit and spices. Take half the cherry-stones, mash them in a mortar, and add them to the other ingredients. Let the stone bottle, or jar, in which these materials are contained be closely covered. Stir it up, or shake it frequently. When it has remained two months pour it off, press the residuum, and filter it. It may then be put into bottles and corked. Some add the leaves of peach and black currant.

3802. *Cherry Brandy of the ordinary kind.*—Procure morello cherries, or small black cherries, but the former are the best; pick them from the stalks, and pierce each cherry with a needle; fill bottles with them nearly up to the necks, and pour in as much of the best brandy as the bottles will hold. In three weeks or a month strain off the spirit; add to it clarified sugar in the proportion of a pound to each quart; flavour to your taste with cinnamon or cloves. The flavour will be extracted from the kernels, although they have not been broken. Some use whiskey instead of brandy.

SUBSECT. 12.—*Cordials.*

3803. The following compounds are intended to be used rather in a medicinal way than any other. They may be prepared either by distillation or by infusion. We shall give directions for both.

3804. *Anise-seed Cordial.*—Put into a still one pound of bruised anise-seeds; proof spirit, six gallons; water, half a gallon; draw off five gallons with a moderate fire. By infusion: add three quarters of an ounce of oil of anise-seed, and four pounds of refined sugar to eight gallons of rectified spirit; fine with an ounce of alum.

3805. *Caraway Cordial*, by distillation, is made as the last: some add orange peel. Or, mix together three quarters of an ounce of oil of caraway, and four pounds of sugar; add ten drops of oil of cinnamon, two drops of the essential oil of orange, and as much of that of lemons; fine with alum.

3806. *Cinnamon Cordial.*—Dissolve one pennyweight of oil of cinnamon with sugar as above; add to it three quarters of a pound of rectified spirits, half an ounce of orange peel, and as much lemon peel, with the same quantity of cardamom seeds; put one gallon of water to this. Fine with alum, and if you wish it coloured, add some burned sugar.

3807. *Citron Cordial.*—Beat up half an ounce of essence of lemon, and as much of that of oranges, with three or four pounds of refined sugar; add to this a quarter of a pound each of dried lemon and orange peel; infuse this in six gallons of rectified spirits that has stood upon seven pounds of figs for a week; if required, add some water.

3808. *Geneva without Distillation.*—Take one ounce of the oil of juniper, and half an ounce of the oil of sweet fennel, three quarters of an ounce of oil of turpentine; and first beat up these with refined sugar, and then add to them one pint of strong spirit of wine. Put this to twenty gallons of proof spirit, and sugar to taste; fine with an ounce and a half of alum.

3809. *Gin Bitters.*—Mix with refined sugar half an ounce each of the essence of lemon and orange peel, a drachm of oil of wormwood, half a pound of dried orange peel; add this to five gallons of the best gin, and let the whole remain together for a fortnight, when it will be ready for use. Dilute it with water to the taste.

SUBSECT. 13.—*Legal Enactments respecting Spirits.*

3810. *The Manufacture of Spirits is under the surveillance of the Excise.*—The regulations are very complicated, and therefore every one carrying on any part of the trade should have a copy of the act of Parliament describing them in his possession. The duty on British spirits at present is 7*s*. 6*d*. per gallon.

3811. All persons not being licensed distillers, rectifiers, or compounders, having more than eighty gallons of spirits in their possession, shall be deemed dealers in spirits, and subject to the survey of the officers of the excise, and to all the regulations, penalties, &c., to which such persons are liable. Dealers in British spirits are prohibited selling or having in their possession any plain British spirits, except spirits of wine, of any strength exceeding the strength of twenty-five per cent. above hydrometer, or of any strength below seventeen per cent. under hydrometer proof; or any compound spirits, except shrub, of any greater strength than seventeen per cent. under hydrometer proof. No retailer of spirits, or any other person licensed or unlicensed, shall sell or send out of his stock or custody any quantity of spirits exceeding one gallon, unless the same be accompanied with a true and lawful permit, under pain of forfeiting £200. Brandy and rum, or any other foreign spirits, are seizable if sold by the dealer, or found in his possession under a certain strength, which is seventeen below proof by the hydrometer. But notwithstanding this, sugar is often added, which prevents the hydrometer showing its want of strength.

Subsect. 14.—*Various Spirituous Liquors prepared in different Countries.*

3812. Although it may not appear necessarily to belong to the subject of domestic economy to describe the spirituous liquors made in distant countries, yet some account of the most remarkable of them may be useful, as they are frequently mentioned.

3813. *In Europe*, besides those which we have described, there are some other spirituous liquors less known. In Dalmatia, a spirit is distilled from the marc of grapes and aromatic herbs called *Rakia*. In Zara, the famous *Maraschino* is made from cherries. In Dantzic, and many parts of Germany, an agreeable compound spirit called *Rosolio* is made from the juice of the plant called Ros salis, brandy, sugar, or honey, cinnamon and cloves, nutmegs, and other ingredients distilled. In Germany, they make also a liquor named *Troster*, from the marc of grapes fermented with ground rye or barley. *Gold wasser* is a spirituous liquor made from grain rectified upon anise seeds, cinnamon, and other spices; it derives its name from their keeping bits of gold leaf floating in it. In Brunswick, *Mum* is made from fermented wheaten malt and oatmeal, with fir rind, tops of fir and beech, and a variety of herbs. In Russia, they make *Braga* from oatmeal and hops fermented, and also *Mead* from honey and beer lees; their *Quass* is from barley malt, rye malt, and oatmeal, fermented and made acidulous. In Norway, the climate is too cold for the production of grain in sufficient quantity to answer the purposes of distillation; but there the inhabitants make a beverage from the fermented juice of the birch-tree, which grows in immense forests: among the better class, wine and lemons are used in the making of this liquor. Potatoes are likewise used in Norway for distillation. The *Snaps* of Denmark and Holstein is distilled from rye and barley. In Turkey, wine and spirits being forbidden by the laws of Mohammed, *sherbet* is made from sugar, lemon juice, apricots, or plums, and flavoured with some sweet flowers.

3814. *America.*—Besides the usual beverages of Europe, a liquor called *Pulque* is made in Mexico and Peru from the juice of the Agave or American aloe. By distilling the Pulque a very strong spirit is obtained called *Aquardiente de Magny*. They likewise ferment a liquor from maize; and this is said to have been done prior to the discovery of America by the Europeans. In Brazil they prepare an intoxicating spirit called *Grape* from sugar, water, and the leaves of the Akaya-tree. A beer called *Chica* is made by the Indians, and also one from the roots of the Manioc or Yucca. The Batata root affords the *Vintro da Batatas*. In North America they make a great deal of what they call brandy from peaches. In the West Indies the negroes prepare a kind of beer from the Cassava, which furnishes the tapioca.

3815. *Asia.*—The arrack of India has been already described. In Nepaul, *Phaur* is distilled from wheat or rice, and *Sihee* from the grape. In Afghanistan a spirit is obtained by fermenting sheep's milk. In Persia a strong spirituous liquor is distilled from peaches fermented; and although the Mohammedan religion forbids the use of wine, and that sherbet is the general beverage, yet several kinds of wine are made by Jews, and drank privately. In Japan, Birmah, Siam, and some of the Eastern islands, arrack is made in abundance. In Kamtschatka a spirit is made from a species of sweet grass, which grows six feet high, with a jointed hollow stalk containing a great deal of sugar.

3816. The Chinese make beer from barley and wheat, called *Tar-a-sun*, and also use hops to preserve it. Beer is also made there from rice, in which they sometimes infuse the seeds of thorn apple (*Datura Stramonium*) to add to its narcotic power. They also make vast quantities of arrack from rice, but use it, in general, with great moderation. The cultivation of the vine has been practised in China from time immemorial; but, in 1373, the Emperor Tay-tsu ordered most of the vines to be rooted out; and they were beginning again to be cultivated when Lord Macartney visited the country. They likewise ferment palm juice into a kind of wine called *Cha*. Although they manufacture much sugar, they have not yet learned the art of making rum from the refuse.

3817. The Tartars prepare a beverage called *Koumiss* from mare's milk: since milk contains a small quantity of sugar, it is not surprising that it should be capable of the vinous fermentation, although this fact is not generally known.

CHAPTER IX.

VARIOUS ORDINARY BEVERAGES.

3818. Besides wines and malt liquors, there are various beverages in common use, of which it will be useful to give some description.

3819. *We shall divide these into three classes:* 1. Beverages of the simplest kind, not fermented; 2. Beverages, consisting of water, containing a considerable quantity of carbonic acid; 3. Beverages composed partly of fermented liquors.

SECT. I.—BEVERAGES OF THE SIMPLEST KIND, NOT FERMENTED.

3820. *Water.*—We refer the reader to medical writers for the particular value of water as a beverage; by these it is described as the best and most wholesome beverage that exists. In Book VIII., Chap. I., we gave a description of the various kinds, such as rain water, spring water, &c. It may be proper here again to observe that no water whatever is absolutely pure; the freer, however, from extraneous matter, the better, except that it should not be deprived of the common air, of which it usually contains a portion; consequently, newly-distilled water is not desirable, nor water that is just produced from thawed ice or snow; such water should be exposed for a day or two to the atmosphere, that it may absorb air, which appears to be essential to it as an agreeable beverage. Spring water is the most agreeable, from its general purity and coolness; but all spring water is not fit for drink, as it often contains various salts. The water of rivers is, in general, good, particularly when filtered; so also is rain water; stagnant is the worst; it is necessary to boil water only when it contains salts which require to be precipitated.

3821. There are certain cases in which an infusion or decoction of some substances in water for drinking are proper, either to remove the vapid taste of water alone, which is sometimes not agreeable to those who are not used to it, or to give it some other property. Preparations of this kind are extremely numerous, and most of them are well known; nevertheless, we consider it proper, in a work of this kind, to collect them, or at least to speak of such as are most useful.

3822. *Toast and Water.*—Bread, highly roasted before the fire, so as to become deep brown, but not burned black, is in a slight degree soluble in water, and will communicate to it a faint tinge. The toast should be put into the water; if the water be poured on the toast, it breaks it, and makes the water thick; this may be drunk as soon as it has cooled sufficiently: it will not keep, acquiring a disagreeable taste after a day. Hard biscuit, browned by the fire to a coffee colour, has been recommended by Sir Anthony Carlisle for this purpose. A small piece of lemon peel is sometimes added.

3823. *Barley Water.*—This is a very ancient beverage, and formed the principal "ptisan" of the old physicians. Hippocrates recommended it as preferable to every other aliment in acute disease, and it still retains its character. The husk of barley contains an acrid resin, and to get quit of this, and render the starch of the grain accessible to water, the external cuticle is taken off, and the kernel, when rounded in a mill, is called *pearl barley*. Pearl barley, therefore, consists only of the starch of the grain, with a minute portion of mucilage and sugar. By slow boiling, a considerable part of it is dissolved, and according to the quantity used, the water is thickened in a small degree with the viscid paste. To prepare barley water, wash a handful of barley, either the common or the pearl barley, and simmer it gently in three pints of water till it is reduced to a quart, which may take an hour. It may be flavoured with a little lemon juice and sugar, or with lemon peel, or cinnamon. It must be used fresh, as it will not keep above a day. To make the barley water of a better colour, it may first be boiled for a few minutes in water that may be thrown away. Some prefer, instead of simmering the barley, to make merely an infusion, by pouring boiling water upon it as in making tea, and then letting it stand till it is cold. Figs, liquorice, or raisins make an addition that may be agreeable to some; or currant jelly may be added as a cooling drink.

3824. *Eau Sucré.*—Water with sufficient sugar dissolved in it to make it sweet is a beverage much used by French ladies, and is considered as very wholesome and refreshing. It is usual for men and women in France to take some of this just before bedtime.

3825. *Lait Sucré.*—Milk well boiled with sugar, and flavoured with lemon: taken cold.

3826. *Cheese or Milk Whey* is an excellent drink in the summer season; so is *butter-milk*, especially in the spring time when the cows have good fresh herbage. In Northern countries, butter-milk is kept till it becomes sour and separates into a curd and whey; this whey has a considerable quantity of acidity, but is nevertheless exceedingly wholesome, and forms a refreshing beverage. It is a common drink of labourers in the north.

A pleasant acidulous whey may be readily procured, by adding to a glassful of milk a little solution of citric acid, or lemon juice, which will curdle the milk. Care must be taken not to add too much acid; an experiment or two will readily show the quantity necessary to effect the purpose.

3827. *Milk*, and *Milk and Water*, are invaluable drinks.

3828. *Lemonade.*—This favourite beverage is easily made, and extremely refreshing. To make a quart, take two lemons, or more, according to taste; pare off thinly a little of the rind, or rub lumps of sugar upon them. Squeeze out the juice of the fruit, and mix it with two ounces of white sugar, including what has been rubbed upon the lemons, add the water boiling hot, and when sufficiently cool, strain the liquor. This may be diluted with water to the strength required. If lemons are not in season, sirup of lemons may be used, or the crystallized citric acid and sugar, adding a few drops of the essence of lemon. Like all drinks of this kind, it is rendered more refreshing by being iced; it may be kept bottled.

3829. *Orangeat*, or *Orange Sherbet*, is made nearly as above, only using oranges instead of lemons; some prefer it to lemonade.

3830. *Sherbet* is a favourite Eastern beverage, universally used among wealthy Mohammedans, to whom the Koran forbids the use of wine. It consists of water, the juice of lemon, orange, or other fruits, with sugar, flavoured farther with honey, spices, and even perfumes. Its agreeable acidity, blended with sweetness, renders it well calculated for assuaging thirst in a warm climate. The poorer classes, who cannot afford to have it so rich, drink water prepared by a little sugar and fruit juice. In India this is carried about in goats' skins for sale.

3831. *The juice of the apple and pear*, it has been suggested by Mr. Knight, might be used with great advantage for preparing a beverage. He has frequently, he says, reduced it by boiling to the consistence of a weak jelly; and that in this state it has remained several years without the slightest apparent change, though it has been intentionally exposed to much variation of temperature. A large quantity of the inspissated juice would, he observes, occupy but a very small space; and the addition of a few pounds of it to a hogshead of water would probably, at any time, form a liquor a good deal similar to cider or perry. It might also, he thinks, be used to supply the place of *rob of lemons* and *oranges*; and might be obtained at a much lower price. It would be useful in long voyages, and this hint might be advantageously used in domestic economy for obtaining an agreeable beverage.

3832. *Summer Cooling Beverage.*—Bruise any fruit you like, as cherries, currants, strawberries, raspberries, &c., add water and sugar to your taste, and strain it; it should be kept in a cool place: or dissolve fruit jelly or rob in boiling water, and let it cool.

3833. *Capillaire* is so called from being prepared from a species of fern called *Capillus Veneris*, or *maiden hair*, a native of Britain; but almost any other fern may be substituted for it. The decoction is considered as pectoral and slightly astringent; it is thought to be useful in allaying the tickling of a cough. The true capillaire made of a sirup of this, flavoured with orange-flower water, has generally been brought from France; and a sirup of the Canada sort, made with maple sugar, is sometimes received from America. A pleasant summer beverage is made by adding a spoonful of capillaire to a tumbler of water.

3834. *A liquid called Capillaire* is also made thus. Beat up sixteen pounds of white sugar and six eggs in three quarts of water; boil it to a sirup, and skim it well; add the eighth part of a pint of orange-flower water, or rose water. This is useful to sweeten liqueurs, or to make a pleasant summer draught with water and lemon juice.

3835. *Orgeat.*—This is made of sirup of almonds, mixed with water that has boiled and become cold, in the quantity most agreeable to the palate; a table-spoonful of it in a tumbler of water makes an excellent drink. The sirup of almonds may be made thus: Blanch and pound in a marble mortar one pound of Jordan almonds and one ounce of bitter almonds; add a spoonful or two of orange-flower water. Mix a pint of rose water with another of spring water, add this to the almonds, and pass the whole through a lawn sieve. Then boil three pints of clarified sirup, and, when it boils, put in the almonds, and let them boil one minute: when cold, put it into bottles, and cork it for use. To make it expeditiously for immediate use, pound the almonds as above; mix them with a quart of water, one of milk, and one of clarified sirup or capillaire; pass through a sieve.

3836. *Vinegar and Water.*—It is commonly known that cold water is dangerous when used by persons heated with labour or by any severe exercise; and yet it is necessary to supply the waste and exhaustion of perspiration in some way or other. When spirits or wine are added in small quantities to water, it may be used, even if cold, with little danger; but severe labour or exercise excites a degree of fever, and that fever is increased by spirits or fermented liquor of any kind. On this account, Dr. Rush, in a publication, recommended that labourers in the fields, particularly at harvest time, should allay their thirst by water containing a small quantity of vinegar, about a tea-spoonful to half a pint of water, which would have the desired effect without stimulating or increasing the heat of the body; and he states that those labourers who have used this beverage have found themselves more refreshed, and less exhausted at night, than when they drank water with spirits. This is not a modern practice merely; for the Romans used vinegar to mix with water for the drink of their soldiers. M. Denon informs us that he experienced great benefit from a drink made of vinegar, water, and sugar when in the burning climate of Upper Egypt. In some districts of England and Scotland, the labourers during harvest use no other beverage than milk and water, butter-milk, or whey, often sour; and, though they are glad to get beer or ale, confess that they are sooner thirsty again after drinking either than after milk and water or whey.

3837. *Raspberry Vinegar and Water.*—Raspberry vinegar is made by squeezing the juice of three quarts of raspberries into a quart of vinegar, and then simmering the vinegar for about a quarter of an hour, with two pounds of sugar, in an earthen pipkin not glazed with lead. When cold, it is to be corked; and a small spoonful of this in a glass of water makes a very cooling and refreshing drink.

3838. *Cream of Tartar* is much used for a cooling drink in warm weather: sugar and the rind of lemon may be added. Half an ounce of cream of tartar will do for a quart of water, which should be boiling; strain when cold.

3839. *Table Beer*, when fresh, is perhaps, upon the whole, the very best, or at least the most wholesome common beverage we have; and it was so considered by the late Dr. Babington.

SECT. II.—BEVERAGES CONSISTING OF WATER IMPREGNATED WITH CARBONIC ACID GAS, TOGETHER WITH CERTAIN SALINE INGREDIENTS.

3840. *General Remarks.*—A class of beverages has of late years come into use, consisting chiefly of water impregnated with carbonic acid gas. It has been long known that many mineral waters, such as the Seltzer and Pyrmont, owe their brisk, sparkling appearance and agreeable acidulous taste to carbonic acid; and to this, likewise, many of their medical virtues are attributed. Experiment has shown that water, under the usual pressure of the atmosphere, absorbs about double its own bulk of this gas when brought into contact with it, and that this absorption is increased considerably by agitation and pressure. It became a practice, therefore, to imitate, by artificial means, these mineral waters, and to use them occasionally as a beverage. The carbonic acid was easily produced, and, by proper apparatus, water was made to absorb it; also, sometimes, those saline ingredients were added which chemical analysis had demonstrated to exist in the natural mineral waters.

3841. *For the purpose of impregnating water with carbonic acid gas, nothing more is necessary* than to put some pieces of pounded marble or chalk into a bottle, *a*, *fig.* 569, and to add some diluted sulphuric or muriatic acid: a glass tube, *b*, bent to a proper shape, must be inserted into the cork of the bottle, through which the gas generated by the action of the acid upon the carbonate of lime can pass into another vessel, *c*, previously filled with water, and inverted, with its mouth *below the surface of water*, in a basin or trough, *d*, *fig.* 569. The gas will expel the water in the vessel *c*, and occupy its place. When the vessel is half empty, cork it under water, and, taking it out, shake the water, which causes it to absorb the air and become acidulous.

Fig. 569.

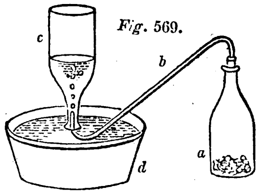


Fig. 570.

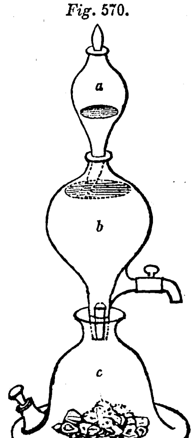

3842. *Nooth's apparatus* was one of the earliest contrivances for causing water to absorb carbonic acid, or making aërated water; and, about forty years ago, this was employed to a considerable extent, and might frequently be seen standing upon the sideboard, preparing a cooling beverage of the same kind as our present soda water, though much less powerful. This apparatus, which may still be useful in imitating mineral waters, and which has an elegant appearance, consists of three glass vessels, *a*, *b*, *c*, *fig.* 570, fitting into each other, yet capable of being easily detached. Into the middle vessel, *b*, is put the water to be impregnated; and into the lower one, *c*, is put some white marble or chalk coarsely pounded, together with dilute muriatic or other acid, which, by its action upon the chalk, sets free the carbonic acid gas which has been fixed in it, and hence had been named "fixed air." The gas thus disengaged ascends through a glass valve in the neck of the vessel *b*, the valves permitting the air to ascend, but preventing the water from coming down: the greater part of the gas is absorbed by the water in *b*, but a part is not absorbed, and this rises through the tube into the upper vessel, *a*, which also contains some water; and, lastly, what still remains unabsorbed escapes through its neck at the top, in which a heavy glass stopper, fitting in loosely, acts as a valve to confine it until its force becomes too great; and thus there is no danger of the glass vessel bursting by the extrication of the gas, which would be the case was there no valve. As the weight of the water in *a* prevents the air from rising into it until it has acquired so much force as to overcome that weight, the gas is subjected to a degree of pressure much greater than that merely of the atmosphere; and hence the absorption is proportionally increased, although this pressure falls far short of the means at present resorted to. By adding iron to the water, a small quantity was dissolved, and thus an artificial chalybeate may be produced; and, by the addition of salts, Seltzer and other mineral waters may be imitated. The prepared water in the vessel *b* is drawn off by a glass stop-cock, and the materials for making the gas are introduced through a glass stopper in the lower vessel. Though this apparatus has been long out of fashion, yet it is within the recollection of many persons still living.

3843. *A great number of simple contrivances* have been invented for the purpose of impregnating water with carbonic acid, one of which consists of a small cask fixed upon a horizontal axis like a barrel churn, which is half filled with pure water; carbonic acid gas is let into this cask through a tube that conducts it from the vessel in which it is generated in the same way as in Nooth's apparatus from chalk or marble and diluted acid. The bung of the cask must be kept open till all the common air has been driven out by the carbonic gas, which may be known by bringing a lighted taper to the bung; if the light is extinguished at once, it is certain that the space above the water is occupied by the gas generated. The bung being now securely fastened down, the cask is whirled round occasionally to agitate the water and increase the absorption. The vessel for generating the gas may be of glass or earthen-ware, as a large bottle; and a safety valve should be contrived some where upon the tube that conducts it to the barrel, to prevent accidents from the elasticity of the gas.

3844. *Impregnating water with carbonic acid, and making what is called soda-water*, is now managed on an extensive scale by manufacturers, who have very perfect apparatus for this purpose, in which considerable pressure and agitation are employed; but, as soda-water is now sold in almost every corner of the kingdom, we do not consider it necessary to detail the mode of operation in making it, as it demands more attention and care, and more expensive machinery than is likely to be resorted to in private families.

[The impregnation of water with atmospheric air has lately been practised in this country, and has been found to furnish a beverage little less attractive, when cooled with ice, than if carbonic acid gas were employed. The same apparatus for introducing the air, and for retaining it by compression, will answer; and either simple water, or that containing a solution of soda, may be used. When drawn from the fountain and mixed with sirups in the usual way, it is not easy to distinguish it from the carbonated water when it is kept sufficiently cold.]

3845. *Single Soda-water* is an acidulous water simply impregnated with carbonic acid.

3846. *Double Soda-water*, which is that now manufactured and sold in tightly-corked bottles, is water having a little carbonate of soda dissolved in it, in the proportion of two ounces to the gallon, and containing carbonic acid gas that has been forced into it by a particular apparatus, with agitation to cause greater absorption. These bottles are corked in a peculiar manner; and, when the pressure of the cork is removed, the gas, by its elasticity, forces out in the manner well known.

3847. *Effervescing draughts* are agreeable imitations of the natural acidulous waters. The best is made by adding a solution of carbonate of soda to some fresh lemon juice. The acid of the lemon attracts the soda from the carbonic acid, the escape of which in a gaseous state occasions the bubbling appearance called *effervescence*. When lemons are in season this is easily made, and forms a very refreshing and cooling beverage much employed in cases of fever, and very cooling in sultry weather.

Lemon juice, containing a great deal of mucilage, cannot be kept long by itself; but as it cannot always be had fresh, means have been found to preserve it in a solid and crystallized state, and a portion of this dissolved, added to the carbonate of soda, is as effectual as the lemon juice itself. The acid of the lemon being the same as that in the citron and lime, it is often named *citric acid*, from the first of these fruits, in which it exists very abundantly, and from which it is prepared in a concrete state. The concrete acid being extremely portable, is very useful to travellers, particularly in long sea voyages; and lime juice is much used in the navy as a preservative from scurvy.

The best modes of making this agreeable and useful beverage is the following: Into a half-pint tumbler of water stir thirty grains of *carbonate of soda* powdered, and into another similar glass squeeze the juice of half a good lemon, or twenty-five grains of crystallized acid of lemon (citric acid) powdered. When the powders are quite dissolved, pour the contents of one glass into the other; a brisk effervescence will take place; drink immediately. It must be observed that the first tumbler must be large enough to hold also the contents of the second. If it be required stronger, increase the quantity of each material. The proportions of each should be so managed that neither an alkaline nor an acid should predominate, except, for some reason, an alkaline or an acid draught is required. This beverage may be agreeably flavoured by dissolving a little raspberry or red currant jelly in the water before the salts are put in; and if these be preferred, a little tincture of ginger, or sirup of ginger, a bit of sugar rubbed on a lemon, or a little white wine. Ten drops of *tinct. ferri muriati* added will form a chalybeate. It is to be observed that the crystallized citric acid contains none of the agreeable aroma of the fruit, as that resides solely in the skin.

3848. *A cheaper mode of making effervescing draughts*, now become very general, is by using the *tartaric acid* with the *carbonate of soda* instead of the citric, and papers of each, containing the proper quantity for taking at one time, are commonly made up in packets of different colours, and sold at all the chemists and druggists' shops under the name of *soda powders*.

3849. *The tartaric acid exists in the juice of several acidulous fruits*, particularly in the grape. It is chiefly procured from the crude tartar which is deposited in the making of wine. (See Wine, Book VIII., Chap. IV.) This tartar is the tartaric acid in combination with potash, that existed in the grapes from which the wine was made. To procure the acid pure, the tartar is dissolved in boiling water, and chalk or lime is added; this decomposes the tartar, and tartrate of lime is obtained, which is afterward decomposed by sulphuric acid, which takes away the lime, leaving the tartaric acid free.

3850. *Ginger Beer for keeping.*—Take five gallons of good water, six pounds of loaf-sugar, three ounces of sliced or powdered ginger, boil them together for half an hour. Peel six lemons, add the peel, and boil for another quarter of an hour. A few minutes before taking it off the fire put in the lemon juice; and when the whole has cooled down to the temperature of new milk, pour it into a cask, and add to it half a pint of good yeast; stir it well together, and let it work for two or three days, according to the weather. Then strain it off from the lees into another cask, and add to it a pint of brandy. Hang in the cask a little isinglass in a muslin bag, and stop the cask down for three weeks; then bottle in stone bottles, cork, and wire it. It will be fit for use in forty-eight hours. This is, in fact, a weak sugar beer, flavoured strongly with ginger and lemon peel.

3851. *Common Ginger Beer.*—Take one ounce of powdered ginger, half an ounce of cream of tartar, one pound of white sugar; mix these in a gallon of water, and simmer it over the fire for an hour; when cooled to milk-warm, add a table-spoonful of yeast, and ferment it for twelve hours. Then put it into stone bottles, cork, and tie it well down. It will be fit for use in forty-eight hours.

An imitation of Ginger Beer is made by means of what are called *ginger beer powders*, which are likewise sold. Take eight grains of finely-powdered ginger, twenty-six grains of carbonate of soda, and one drachm of white sugar; powder these in a mortar, mix them intimately, and dissolve them in a tumbler half filled with water. Then add the tartaric acid, as above described in the soda powders.

3852. *An agreeable beverage may be made*, which will be useful in hot weather as a light summer drink, by mixing a bottle of ale or porter with ten quarts of water, adding a pound of coarse brown sugar and two ounces of ginger. This is not exactly ginger beer; but if well mixed, then bottled and corked, it will be found to be brisk, and fit for drinking in a few days.

SECT. III.—BEVERAGES COMPOSED PARTLY OF FERMENTED LIQUORS.

3853. *Hot spiced wines* were much in use till the beginning of the sixteenth century; and some of these favourite compounds were known by the names of *ypocras*, *sack*, and *clary*. The first of these, which took its name from the bag through which it was strained, called by apothecaries "Hippocrates's sleeve," was made either of white or red wine with aromatics, such as ginger, cinnamon, aromatic seeds, and sugar. Clary was made from claret, with honey and aromatics; and sack from the wine of that name, a kind of sherry. These were drunk as a "night cap," and at the conclusion of a banquet. Le Grand, in his "Vie privée des François," observes that the poets of the thirteenth century speak with rapture of these delicious beverages; and it is said that they were highly esteemed in convents and universities. A scale of perfection was even observed: when the compound was made of Bordeaux wine, it was simply called *Bishop*; but received the name of *Cardinal* when old Rhine wine was used; and rose to the dignity of *Pope* when imperial Tokay was employed. The vestiges of these ancient mixtures may still be seen in our mulled wine and bishop.

3854. *To mull Wine.*—Boil the spices (cinnamon, nutmeg grated, cloves, and mace) in any quantity approved, in a quarter of a pint or better of water; put to this a full pint of port, with sugar to taste. Mix it well, and serve hot with thin slips of toast or rusks. Lemon or orange juice may be added, and the water may be strained off from the spices. *Ale or porter may be mulled* as above, and have toasts or biscuits put to them.—(*Meg Dods.*) Formerly the yolks of eggs were mixed with mulled wine, as in making custard or egg-caudle, and many flavouring ingredients were employed which are now disused.

3855. *Bishop.*—The day before it is wanted, grill on a wire-grill, over a clear, slow fire, of a pale brown, three smooth-skinned, large, bitter oranges. Place them in a small punch-bowl that will about hold them, and pour over them a full half pint from a bottle of old Bordeaux wine, in which a pound and a quarter of loaf sugar is dissolved. Cover with a plate. When it is to be served next day (though it may lie over two or three days), cut and squeeze the oranges into a small sieve placed above a jug, containing the remainder of the bottle of wine, previously made very hot; add more sirup if it is wanted. Serve hot in large glasses, or in summer it may be iced. Bishop is often made of Madeira in England, and is perfumed with nutmegs, bruised cloves, and mace. It ought, however, to be made of old generous Bordeaux wine, or it fails of its purpose as a tonic liqueur. It is reckoned highly stomachic, and is served at French dinners, *savans* and *récherchés*, either as the *coup d'après* or after the dessert.—*Meg Dods.*

3856. *The wassail bowl* of ancient times was made of mild ale, well spiced and sweetened; and sometimes with eggs beat up in it.

3857. *The ancient Ypocras* was made of a quart of red wine, an ounce of cinnamon, half an ounce of ginger, a quarter of an ounce of pepper, and half a pound of sugar, all put into a bag and infused in the wine.

3858. *Cool Tankard.*—The composition of this ancient beverage is of great variety. The basis is home-brewed ale, spices, and seasoning herbs. To a quart of good ale, add a glass of white wine, and another of brandy, some lemon juice, and the rind pared very thin; a little well-toasted bread; a sprig or two of burrage or balm, and a little nutmeg grated. Some use cider instead of ale.

3859. *Egg Flip.*—Heat a quart of good home-brewed or other ale, and pour it into a jug with a spout; in a similar jug beat up three or four eggs with a quarter of a pound of moist sugar, and one or two glasses of rum or brandy, flavouring it with nutmeg, ginger, and grated lemon peel. When the ale is quite hot, but not boiling, pour it quickly into the jug with the eggs, return this back again into the other jug, and thus keep pouring the mixture backward and forward from one jug to another, till the whole is thoroughly incorporated, and as smooth as cream.

3860. *Egg Hot.*—This is made in the same manner as the last, only there is no spirits nor spices; simply the egg, and ale or beer, with sugar.

3861. *Ale Posset.*—Boil a pint of new milk with a slice of toasted bread; pour a bottle of mild ale into a punch-bowl, sweeten, and add spices, and then pour the boiling milk over it. A fine head should rise.

3862. *Sack Posset.*—Boil some cream and grated sweet biscuits; add sugar, cinnamon, and nutmeg. Warm some sherry, and stir it into the cream; then pour the whole quickly from one vessel to another until it be perfectly smooth; or it may be made with eggs beat up in milk instead of the cream.

3863. *Punch is a beverage made of* various spirituous liquors or wine, hot water, the acid juices of fruits, and sugar. It is considered to be very intoxicating; but this is probably because the spirit being partly sheathed by the mucilaginous juice and the sugar, its strength does not appear to the taste so great as it really is. Punch, which was almost universally drunk among the middle classes about fifty or sixty years ago, has almost disappeared from our domestic tables, being superseded by wine.

3864. *English Punch.*—Rub the yellow rind of a lemon with lump sugar; put this sugar into the punch-bowl, and squeeze the lemon juice to it, add the spirits, rum and brandy, in such proportions as are preferred, incorporate the spirits thoroughly with the sugar and lemon before pouring in the boiling water, and keep stirring the whole while this is pouring: some add Madeira or sherry. Punch is kept also cold in bottles, and in summer is very agreeable. In Scotland it is frequently made with whiskey. Where fresh lemons cannot be had for punch, or similar beverages, crystallized citric acid, and a few drops of the essence of lemon, will be very nearly the same thing.

3865. *Regent's Punch.*—A bottle of Champagne, a quarter of a pint of brandy, a glassful of *veritable Martinique*: with this mix a pint or more of a strong infusion of the best green tea strained, and capillaire or simple sirup to taste.—*Meg Dods.*

3866. *Norfolk Punch.*—Pare thirty-two Seville oranges, and the same number of lemons; infuse the peel for two days in a large bottle or jar with a gallon of brandy (or flavourless whiskey), a little reduced in strength; clarify in a gallon of water four pounds of sugar; when cold, strain the brandy (which will now be a tincture) to this; add the juices of the oranges and lemons, previously strained and bottled, when the peel is taken off; cask the liquor, or put it in a jar, and stop it well; in six weeks it may be gently poured, or drawn off, and bottled. A tincture of bruised nutmegs and cloves may be added to this compound; this will keep any length of time, and in any climate.—*Meg Dods.*

3867. *Milk Punch.*—Rub off on lumps of sugar the zest of a dozen lemons; pare off what you do take off on the sugar, but take none of the white stuff; infuse in two quarts of brandy; strain off in two days, and add of clarified sirup two pounds, and of water two quarts, with half a pint of hot new milk; strain through a jelly bag, and keep in a close jar or small cask till it fines, which will be in six weeks or less. Milk punch may be made extempore by adding a little hot milk to lemonade, and straining through a jelly bag; it is generally drunk cold.

3868. *Wine Punch.*—Port wine, two pints; arrack, two pints; the juice of twelve lemons; sugar, one pound; hot water, six pints.

3869. *Tea Punch.*—Hot tea, two pints; arrack, thirteen ounces; sugar, four ounces; flavoured by rubbing off the yellow peel of the lemons; or green tea, juniper, and Champagne.

3870. *French Punch.*—Cut a lemon into thin slices, taking out the seeds; boil them in water, and add a pinch of green tea, and let it infuse five minutes; strain the whole, and add brandy and sugar sufficient.

3871. *Auld Man's Milk of Scotland, or Egg-nog of America.*—Beat the yolks and whites of six eggs separately; put to the beat yolks sugar and a quart of new milk, or thin sweet cream; add to this rum, whiskey, or brandy, about half a pint; put in the whites of the eggs whipped up, and stir the whole gently. It may be flavoured with nutmeg or rind of lemon.

3872. *Sangaree* is a kind of punch frequently drunk in the West Indies, and is composed of half Madeira and half water, acidulated with lime juice and sweetened with sugar.

3873. *Mint Julep of North America*, from Capt. Marryatt.—Put into a tumbler about a dozen sprigs of the tender shoots of mint; upon them put a spoonful of white sugar, and equal proportions of peach and common brandy, so as to fill up one third, or perhaps a little less. Then take rasped or pounded ice, and fill up the tumbler. Epicures rub the lips of the tumbler with a piece of fresh pineapple, and the tumbler itself is very often incrusted outside with stalactites of ice. As the ice melts, you drink. The Virginians, says Capt. Marryatt, claim the merit of having invented this superb compound; but from a passage in the Comus of Milton, he claims it for his own country.

3874. *Rum Shrub and Water.*—Rum shrub is made from the juice of lemons, with rum and sugar, but oftener of the juice of the lime, rum, and sugar. Great quantities of lime juice with rum are imported from the West Indies, for the purpose of making shrub and other liquors. A small quantity added to water makes an agreeable beverage. *Brandy Shrub* and *Currant Shrub* are made in a similar manner.

3875. *Spirits and water* warm, or cold as *grog*, are well known.

CHAPTER X.

ON TEA.

Sect. I.—History of the Introduction of Tea into Britain.

3876. *The beverage so named, and now become almost a necessary of life* in a great part of the British Isles, was wholly unknown to the Greeks and Romans, as likewise to our ancestors previously to the middle of the seventeenth century.

3877. *The date of its beginning to be used in this country* is well ascertained by the fact that a duty of eightpence per gallon was, in 1660, laid on the infusion of tea made and sold in coffee-houses in London; and that its use had not at that time become very general, is shown by an entry in the published diary of Mr. Pepys, secretary to the Admiralty: "September 25th, 1661.—I sent for a cup of tea (a China drink), of which I had never drunk before."

3878. *It does not appear clear by whom tea was first imported into Europe.* We learn from Mickle, in his "Introduction to the Lûziad," that the Portuguese, who had intercourse with China in 1517, were allowed to purchase silks, porcelain, and tea; but we have no evidence how far they availed themselves of this privilege with respect to the latter. That they were acquainted with the use of an article in such general consumption among the Chinese is rendered very probable from the circumstance that they are the only European nation who designate the plant by its national name of *tscha*, all others applying to it the provincial name of *te*, derived from the dialect of Tokien, the province with which the English and Dutch maintained their earliest intercourse. The Dutch arrived for the first time in China in 1601; but there is no authentic evidence that either they or the English, who appeared about the same time in the Eastern seas, imported tea during the first half century of their intercourse with the East. No doubt, however, from the facts we have noticed, it was brought to Europe about that time, and that the taste for it was beginning to spread in 1660.

3879. It was, however, so rare a commodity in England in 1664, that the English East India Company at that time brought two pounds two ounces of it as a present for his majesty; and it was not imported direct from China, but from Holland. In 1666, Lord Arlington and Lord Ossery brought over from the latter country a quantity, at which time it was sold in England for sixty shillings a pound. The Dutch procured it from Bantam, then one of the principal emporia of India, and much frequented by the junks or ships of Canton. But it was scarcely then considered as an article of commerce: for in 1667 we find that the East India Company gave the first order to their agent at Bantam to send home 100 pounds of tea for the purpose of making "presents to their friends at court."

From that time the consumption increased; and in 1678, nearly 5000 lbs. were imported: a quantity, however, which is now easily sold annually by a single shop in London. As a proof of the rapidly-increased demand for what had become a favourite article of luxury, about the end of the century nearly 20,000 lbs. of tea were brought every year to England; and in twenty years more the annual importation exceeded 1,000,000 lbs. The present enormous consumption in England of upward of 49,000,000 lbs. annually is perhaps greater than the quantity consumed in all the countries of the world besides, except China. The amount of the duty on tea in the year is about 4,603,000*l.*

Sect. II.—Tea Plant, and its Cultivation.

3880. *With respect to the tea plant* (*Thea*, Linn.) we have, until lately, been deficient in accurate information, as it was only cultivated in China and Japan, countries to which strangers are not permitted free access.

Linnæus was induced to think that there were two species, one of which produced the black, and the other the green teas; but later observations do not confirm this, and from various information received concerning the tea plant, some botanists are of opinion that the various qualities of teas depend upon varieties produced by soil, climate, and the age at which the leaves are plucked, as well as upon the management of them afterward; in short, that a single species has, like most other useful plants long cultivated, spread into several permanent varieties, two of which, the black and the green, distinguished by broad and narrow leaves, are chiefly known to us: these grow in different districts. When the leaves of black and green tea are expanded by hot water and examined by the botanist, though a difference of character is perceived, yet this is not sufficient to authorize considering them as distinct species.

3881. *The tea-tree or shrub belongs to the class and order* of Monadelphia Polyandria in the Linnæan system, and to the natural order of Aurantiaceæ in the system of Jussieu. Lately it has been made into a new order, the Theasia, which includes the Camellia and some other plants. It commonly grows to the height of from three to six feet; but it is said that in its wild or native state it reaches to twenty feet or more. In China it is cultivated in numerous small plantations. In its general appearance, and the form of its leaf, *fig.* 571, it resembles the myrtle; the blossoms are white and fragrant, not unlike those of the wild rose, but smaller, and they are succeeded by soft green capsules, containing each from one to three white seeds. These capsules are crushed for oil, which is in general use in China.

Fig. 571.

3882. *The tea-tree does not require a tropical climate,* but flourishes best in temperate regions. In China, where it is indigenous, the greatest part of the tea grows between the twenty-seventh and thirty-first degrees of north latitude, though the plant thrives to the north and south of these parallels. It also grows in Japan, Cochin China, Tonquin, and Ava, and it is raised without difficulty in our own green-houses. The part of China where the best tea is cultivated is called by us the "tea country," and consists of portions of five provinces; viz., for black tea, Tokien and Canton, but more particularly the first, where formerly European traders were permitted to resort, until the evils supposed to arise from the intercourse with foreigners induced the Chinese government to restrict all communication to a single port; and for green tea, Kiang-nan, Kiang-si, and Chi-kiang, but chiefly the first of these, that beautiful province of which Nanking is the capital. The worst teas, the bohea, come from Woping, a district in Canton.

In other parts of China, tea, though grown, is of inferior quality compared with that of the above-mentioned provinces, and is raised for local consumption only; or when of a superior kind, it loses its flavour when exported, like some of the fine wines of France.

The more northern part of China, as Pecheli, the metropolitan province in lat. 40°, is too cold for the successful culture of the tea plant; and in the extreme southern parts of China the heat is too great. It is not cultivated farther south than about Canton, where a few small plantations are to be seen. The producton of good tea depends upon soil and locality fully as much as that of good wine; like it, too, the produce varies according to the care with which the crop is collected and prepared for use. The quality of the crop varies also, like the vintage, with the nature of each season.

The best green tea is grown in the district of Hoey-chow-foo, the most southerly city of the province of Reang-nan, and about 700 miles from Canton. The soil in which it is reared is a decomposition of granite abounding in feldspar; and it is remarkable that it is from the same mineral the finest porcelain cups for drinking tea are manufactured. The black tea district is about 200 miles from Canton.

3883. *The cultivation of the tea plant requires great care.* It is raised chiefly on the sides of hills; and in order to increase the quantity and improve the quality of the leaves, the shrub is pruned, so as not to exceed the height of from two to three feet; much in the same manner as the vine is treated in France. They pluck the leaves one by one, selecting them according to the kinds of tea required; and notwithstanding the tediousness of the operation, each labourer is able to gather from four to ten or fifteen pounds a day. When the trees attain to six or seven years of age, the produce becomes so inferior that they are removed to make room for a fresh succession, or they are cut down to allow of numerous young shoots.

In China landed property is very much subdivided; and tea is, for the most part, grown in gardens or plantations of no great extent by proprietors little above the rank of peasants. The leaves, being gathered by the cultivator's family, are immediately carried to market, where they are purchased by a particular class of dealers, who dry them and otherwise prepare them to be sold to the "tea merchants." The latter complete the manufacture, sorting the teas according to their qualities, give them a final drying, and pack them up in chests, which are stamped with the name of the grower or manufacturer, and the merchant who makes them up.

3884. *Teas of the finest flavour* consist of the youngest leaves; and as these are gathered at four different periods of the year, the younger the leaves, the higher flavoured the tea, and the scarcer, and, consequently, the dearer the article.

3885. Perhaps one of the most authentic accounts which we have of the preparation of tea in China is that which was given in evidence before the House of Commons, September, 1834, by Mr. Reeves, who was for many years the East India Company's tea inspector.

"The tea plant in China has two distinct varieties, if not species, which respectively yield the *black* and the *green* teas. The tree is an evergreen. The pickings of the leaves begin in about May, when the plant is in full leaf, but ready to shoot out other leaves. In the black tea plant, the first shoot, or the bud coming out, then covered with hair, forms the fine *flowery pekoe*. A few days' more growth makes the hair begin to fall off; the leaf then expands and becomes the *black-leafed pekoe*. Some young shoots have fleshier and finer leaves, which makes the *Souchong;* the next best leaves make the *Campoi;* the next *Congou*, and the refuse and inferior leaves the *Bohea*. These are the states in which the black teas are collected by the tea farmers; and some very coarse teas used by the Chinese themselves are cheaper than the sloe leaves could be brought to market in this country. The tea of Woping in Canton is of this character. There is a greater difference in the qualities of black teas than of green.

"The varieties of green tea appear to originate, not from the stages of picking, like the black, but partly from difference of treatment and manipulation, partly from difference of soil. A large proportion of *Twankay* is the growth of a different district from that which produces the *Hysons*. When a tea merchant buys green tea from the farmer, he subjects it to the following process: he sifts it through one sieve, which takes out the dust, the *young hyson*, and the *gunpowder*, then through another sieve, which passes the *small leaf hyson* of commerce; two other sieves successively take out the second and largest degree of size, and what does not pass the third forms *hyson-skin*. The teas then undergo the process of firing, in an iron pan, at a great degree of heat, which gives the leaves a lighter twist, and brings them up to their colour. The tea which passes the first sieve is then put into a winnowing machine, and the fan blows the light leaf at the farther end, and the larger broken leaf at a shorter distance. The heavier teas, as the gunpowder and hyson, fall nearer or farther from the hopper, according to their gravity, and are separated by the winnowing machine. When fairly made, the difference between the gunpowder and the young hyson will be this: the young leaf which takes the long twist will form the young hyson, and that which takes the round twist will form the gunpowder. The same mode of manufacture is pursued with respect to twankay tea, the fine leaves of which make hyson."

3886. *Another account states* that the drying of the leaves is begun in the sunshine, after which they are carried into houses erected for the purpose, with charcoal stoves, each being covered with a large flat iron pan, on which, after it is heated to a certain degree, a half or three quarters of a pound of the leaves are put, and stirred about briskly with a kind of brush, to cause them to dry and curl up. They are then swept into baskets and rubbed or rolled between the hands to curl them still more, and again subjected to the heat of the stove. By repeating this process they are made to assume the appearance which we see. There is some difference between the modes of preparing the green and the black teas; but no authentic account of this difference has yet been received in Britain. There is no truth, however, in the report that green tea owes its colour to being dried upon plates of copper, for it is in fact dried upon iron plates. This tea has been carefully analyzed, and chemical tests do not detect any copper, which would thus appear if any existed. It has been stated that some vegetable dyes are sometimes used by the Chinese for the green; and it is asserted that they can make either black or green tea from the same leaves; but however this may be, these two kinds of tea are mostly produced from different plants and in different districts.

3887. *The poorer people of China*, who grow a little tea in their own gardens, it is said, content themselves with drying the leaves in an iron kettle over a slow fire, shaking the kettle as the leaves dry and curl up, and stirring them with their hands; when they judge the tea to be well done, they pack it in baskets, and hang it in the roofs of their cottages. It is not used until it has been kept a twelvemonth.

SECT. III.—VARIOUS KINDS OF TEA IMPORTED.

3888. *The following is a list of the various kinds of tea usually imported* into this country from China, with a statement of the prices paid for them at Canton, beginning with the lowest qualities:

Black Teas.

		s.	d.		s.	d.
Bohea of Woping or Canton	from	0	6	to	0	7
Bohea of Tokein	——	0	9	to	0	10
Congou	——	0	11	to	1	0
Campoi congou	——	0	11	to	1	2
Souchong	——	0	10	to	1	10
Ankoi souchong	——	0	9	to	1	0
Orange pekoe	——	1	0	to	1	4
Caper	——	0	10	to	1	0
Fine flowery pekoe	——	1	10	to	3	2

Green Teas.

		s.	d.		s.	d.
Twankay	from	0	9	to	1	1
Hyson skin	——	0	9	to	1	0
Young hyson	——	1	2	to	1	8
Hyson	——	1	8	to	2	3
Imperial gunpowder	——	1	9	to	2	3
Pearl gunpowder	——	1	9	to	2	5

These names are corruptions of Chinese words; but though they are not the terms employed by the Chinese themselves in their transactions with each other, they are well understood by them in their dealings with Europeans. Sir George Staunton informs us that the names Bohea, Congou, and Souchong are not given by the Chinese, who merely describe these teas as inferior, middling, and superior. These varieties necessarily graduate into each other; and some have supposed that it must be impossible to distinguish them always by the taste; but experience has shown that those whose business it is to taste and discriminate teas at the sales acquire the power of distinguishing pretty correctly the various sorts; sometimes by the smell alone, or, when that is not sufficient, by the infusion.

It is said that in the catalogues of the Chinese merchants there are at least one hundred and fifty names of teas; but many of these express the same sort, and others are invented to impose upon foreigners. Some of these teas are of so delicate a kind, such as the true imperial tea, that their flavour would be destroyed by a sea voyage, and hence they are never brought to us.

The following brief description of the various sorts of tea usually known in Britain may interest the reader.

3889. *Bohea.*—This is so called from the district (the Wo-ee-hills in Fokien, the great country for black tea) where it is principally grown. It is of two kinds, that of Fokien, which is nearly as good as congou, and that of Woping or Canton, which is the lowest quality of tea in the European markets. The last consists of the coarsest and oldest of the leaves, often the refuse, and on this account is the most liable to be adulterated both in China and in this country; it is said to be but little used in London, being mostly sent into the country; it is of a blackish cast, and yields a deep yellow infusion.

3890. *Congou* (*cong-fou*, "made with care").—The consumption of this black tea in England very much exceeds that of any other variety. Its infusion is lighter than that of bohea; the best kind, the Campoi congou, has a very agreeable flavour; but the cheaper kinds somewhat resemble bohea, and are probably often mixed with it.

3891. *Souchong* (*se-ou-chong*, "a very little sort").—This was formerly much imported, and is still so to a certain extent; but it is said that some of the finer kinds have of late almost disappeared from the English market, without any cause being assigned, and that the finer congou is often sold for it. Its infusion is of a greenish colour, and it has an agreeable flavour.

3892. *Pekoe.*—The class of teas which bears the name of Pekoe (*pe-kow*, "white leaf-bud") is the finest of black teas. The flowery pekoe consists of the early buds of the best tea plants, and are sometimes, in parcels intended for presents, intermixed with flowers, supposed to be those of the fragrant olive, which is discoverable in the form of small white particles; its infusion is light, inclining to green, has a violet scent, and very agreeable flavour. This tea is more common in Russia than in England, being chiefly the produce of the north of China: with us it is little used except for flavouring other teas.

3893. *Twankay.*—This is the coarsest of the green teas, and is little used in this country, except by the lower classes. It is said to be the growth of a different district from the hyson. *Singlo* is very similar to twankay.

3894. *Hyson.*—The hysons are the sorts of green tea most usually employed. When good, the infusion is a fine green, with a decided flavour. *Hyson skin* consists of the inferior leaves of the hyson separated in the manufacturing.

3895. *Gunpowder Tea.*—This is the best of the hyson, or green teas, and is so named from the smallness and roundness of the grain. It consists of the first leaves of the vernal crop of the green tea plant. What is brought to England is not mixed with the flowers of any other plant, like the pekoe; but some of the finest green teas imported by the Russians possess this admixture. What is sold for gunpowder tea by many grocers is only hyson of a small grain; and the latter is often employed to adulterate gunpowder tea. Real gunpowder tea should have a small, bright, well-curled leaf, and a very fine flavour.

Several other kinds of tea than those just mentioned are to be met with in lists of teas kept in shops; but these consist chiefly of mixtures of teas of various sorts, and are scarcely to be considered as actual varieties; the dealers, there is reason to believe, producing most of them for their customers, according to the demand, or their skill and ideas of profit. It is probable, likewise, that in future considerable alterations may take place in the varieties and classification of teas; and that the late endeavours to grow tea in other parts of the world, and the discoveries of wild tea in our lately-acquired province of Assam, may tend to this effect.

3896. *Besides the above teas in common use in Britain*, some other less known varieties are occasionally imported. Among these are, *Padre tea*, a very highly-flavoured souchong, made up in pound packets; *Caper Souchong*, scented, made up in the form of balls, and imported chiefly in small boxes; *Cowslip Hyson*, tea scented by the admixture of scented berries, that give it a cowslip flavour, &c.; *Ankoy teas*, grown in *An-khe:* these, though they resemble the teas of Canton, are inferior and cheaper. They are supposed to be gathered from wild tea plants, with which whole districts in China are covered.

3897. *Several plants, it is said, are employed by the Chinese in giving a perfume and flavour to teas;* as the leaves of Olea fragrans, Camellia sesanqua, Polygala thurans, Rhamnus thurans, &c. It appears that different tea farms in China produce teas of various qualities, in the same manner as wine is prepared of different degrees of perfection, according to the vines and skill of the manufacturer. These are often mixed by the Hong merchants, or their agents, to make up the marketable quality.

SECT. IV.—CHEMICAL ANALYSIS OF TEA, AND ITS MEDICAL EFFECTS.

3898. Few things have been more exclaimed against than the drinking of tea, the constant practice of which has been proclaimed to be injurious to the nerves, and debilitating to the constitution; yet the use of this beverage continues. It has been attempted, also, to be shown that it is a useless article of diet to the poor, as being devoid of nutriment, except it may be contained in the milk and sugar used with it; yet some explanation is necessary to account for the great partiality of all, particularly of the poor, for tea. Liebig observes, "We shall certainly never be able to discover how men were led to the use of the hot infusion of the leaves of a certain shrub (tea), or of a decoction of certain roasted seeds (coffee). Some cause there must be, which would explain how the practice has become a necessary of life to whole nations." General experience has proved that it is a valuable diluent, and particularly useful at the commencement of febrile complaints, and, being of a slightly sedative and astringent quality, it is allowed to be peculiarly refreshing after great fatigue. Upon the whole, it is not shown by facts that its effects upon the human constitution, when used in moderation, are of that injurious tendency that has been so frequently alluded to; on the contrary, there is no doubt that, among the lower classes in particular, its substitution for stronger stimulants has been extremely beneficial, and that its character has risen of late in the medical profession. It is, perhaps, less proper for breakfast than for an evening refreshment; and it is not advisable to allow it as a constant morning meal for young people, who require something more nutritive. Strong green tea, however, has remarkable and injurious effects on certain constitutions, producing tremour, distressing feelings, and sleeplessness when taken at night; hence it has been employed by ardent students to resist the desire for sleep.

3899. *Tea, when chemically analyzed, is found to contain* woody fibre, mucilage, a considerable quantity of the astringent principle, or tannin, a narcotic principle, which is, perhaps, connected with a peculiar aroma. The tannin is shown by its striking a black colour with sulphate of iron, and is the cause of the dark stain which is always formed when tea is spilled upon buff-coloured cottons dyed with iron. Lately, a crystallizable and salefiable constituent has been found in tea, which has been called *Theine*, and is supposed to be identical with *Caffeine*, one of the constituents of coffee. Theine exists in tea in combination with tannin, or tannic acid, forming tannate of theine, and is extracted by hot water, but precipitates on the water cooling. Liebig has conjectured that theine, from its containing nitrogen in its composition, and by its combination with oxygen and the elements of water yielding *taurine*, the nitrogenized compound peculiar to bile, may contribute to the formation of that secretion, and hence may perform an important part in the function of nutrition. If this conjecture should prove well founded, it may account for this liquid appearing to possess more nutritive property than has been supposed; why tea so often satisfies the poor as a substitute for animal food; and why females and literary persons who take little exercise manifest such partiality for it; and it would likewise show why none of the substitutes for tea which have been tried have been found equal to it, being deficient in the theine. It does not appear quite certain whether green or black teas contain the greatest quantity of the astringent principle, or tannin; for the analysis of Sir H. Davy gave most to black tea, whereas that of Mr. Brande ascribes the most to the green; the latter opinion is most generally received, though it is probable that the composition of both kinds of tea varies considerably in this respect.

Sect. V.—Adulteration of Tea.

3900. *Chinese tea has frequently been adulterated in this country* by the admixture of the dried leaves of certain plants. The leaves of the sloe, white thorn, ash, elder, and some others, have been employed for this purpose. Other plants have likewise been mentioned, as the leaves of speedwell, wild germander, black currants, syringa, purple-spiked willow herb, sweet briar, and cherry-tree. Some of these are harmless; others are, to a certain degree, poisonous; and the latter are the leaves of all the varieties of the plum and cherry tribe, to which the sloe belongs.

Adulteration by means of these leaves is by no means a new species of fraud; and several acts of Parliament, from the time of George II., have been passed specifying severe penalties against those guilty of the offence, which, notwithstanding numerous convictions, continues to the present time.

To such an extent had this illicit practice been carried, that it has been officially stated in a parliamentary report that upward of four millions of pounds weight of dried leaves were used annually to mix with tea. A patent was even taken out for the preparation of British leaves as a substitute for tea, and extensive works were erected for the manufacture; but it was soon discovered that the leaves so prepared found their way to the grocers, who employed them in adulterating foreign tea, upon which the manufacture was suppressed.

It is by no means easy to detect adulterations of this kind. The best mode is to employ the knowledge of the botanist, by moistening and spreading out carefully, and drying flat the suspected leaves, and then comparing their form with that of genuine tea leaves. The leaves of the sloe are not quite so long, a little rounder in their form, and not so deeply serrated or notched; but their general resemblance is so nearly that of tea leaves, that few, except botanists, could distinguish them; their astringency is greater than that of tea; and though the leaves are poisonous, that is not the case with the fruit, which has been used to adulterate port wine.

These leaves are not the only poisonous substances used; from the evidence given, it appears that in the attempt to imitate green tea, verdigris, and, what is worse, carbonate of copper, a strong poison, had been employed to give them the colour of genuine green tea. The carbonate of copper may be detected by making an infusion, and putting some into water impregnated with sulphuretted hydrogen; the water will acquire a black colour if this salt be present; but no change will happen if genuine green tea is used; we have already stated that it contains no copper.

Although frauds of this kind will probably always be attempted, and therefore it is proper to study the means of detection, yet, as they are always attended with a great deal of risk, another species of fraud, involving no legal penalty, is more commonly practised; this is, deteriorating certain teas, by mixing them with others of inferior quality. It is said that a great deal of twankay and bohea, the cheapest kinds of green and black teas, are disposed of in this way. It is well known that vast quantities of bohea are imported; and as very little of this tea is met with in the shops of London, it is concluded, and we believe not without good reason, that it is extensively mixed with congou. At present there appears to be no method of guarding against these frauds but by purchasing teas of the most reputable dealers.

3901. *The Chinese manufacturers themselves sometimes employ means of adulterating their teas;* and it is said that they dry vast quantities of the leaves of various trees for this purpose. Some tea was brought to this country from Sincapore, which was found to be mixed with other leaves; and this tea had been carried to Sincapore in Chinese junks. Similar frauds had been practised previously; but when discovered by the East India Company, who kept skilful inspectors for the purpose, such teas, when discovered, were never offered for sale, but were destroyed.

Sect. VI.—Consumption of Tea.

3902. The following statement of the consumption of tea in Europe, America, and the colonies is believed to come near to the truth:

	lbs.		lbs.
Great Britain	43,000,000	United States	10,000,000
Russia	6,500,000	British America and West Indies	1,500,000
Holland	3,000,000		
Germany	2,000,000	British India	1,000,000
France	250,000	Australia	250,000

This vast quantity of the leaves of a foreign plant, imported in most instances from a distance of fifteen thousand miles, may cost in China, in round numbers, about four millions sterling; and the total cost to the consumers, including duty, may be about sixteen millions. The Chinese, and the other Oriental nations, use scarcely any but black teas. In Britain, the black tea consumed is to the green as five to one. The Americans, on the contrary, use, in general, two parts of green to one of black. The English in Bengal and Australia use little else than green; and at Bombay and Madras they drink chiefly black tea. In Holland more black tea is used than green; and in Russia the consumption is almost all of black.

Sect. VII.—Purchase of, and keeping Tea.

3903. *Tea should be chosen* by the agreeableness of its odour, and as whole as possible, in order that it may be easily examined as to its leaf; and the greatest care should be taken that it has not been exposed to the air, which destroys its flavour.

The method employed by the Chinese to prevent this is extremely ingenious and effectual. It is well known that it is brought from China in boxes termed tea-chests, made of thin, hard wood, and lined with extremely thin lead, the method of making which is as follows: A man sits on the floor with a large stone slab before him, and a moveable flat stone on its edge. His fellow-workman, who stands by his side, pours a small quantity of melted lead on the slab, and the first workman instantly dashes down the moveable stone on the melted lead, which presses it out into a flat and thin plate, which he immediately removes from the slab; the rough edges of these plates are then cut off, and they are soldered together for use. Considerable dexterity is probably necessary in this operation, which does not appear yet to be imitated in this country. The tea-chests are remarkably strong, from the great toughness of the wood, the manner in which their corners are joined, and their being pasted over with paper. When emptied, they are sold by the grocers, and form remarkably cheap and convenient packing cases for various purposes.

Sect. VIII.—Cultivation of Tea in other Countries than China.

3904. *It had long since occurred to intelligent persons that it would be desirable we should not be wholly dependant upon so singular a nation as the Chinese for tea*, which has now really become an article of necessity. Trials made in several other countries proved that the tea plant might be easily cultivated, the climate required not being tropical.

From the variety of climate in that extensive portion of China where it grows, the tea plant would not appear to be a very delicate shrub, and there does not seem to be any reason why it might not be raised in some of our colonies, among which may be found every variety of climate.

3905. *In 1793 Lord Macartney procured some tea plants from China, and sent them to Bengal*; and, at various times, experiments have been made with respect to the cultivation of the tea plant in India, for which, in many parts, particularly in the Nepaul country, the climate and soil appear favourable.

Mr. Royle, in his "Illustrations of the Natural History of the Himala and Cashmere," has published much collected information respecting the tea plant, and upon the conditions which relate to the vegetation and the cultivation of these plants in China; and, from the whole, the author concluded that, in the Himala country, where so great an analogy exists in latitude, elevation, soil, climate, and the course of the seasons, as well as considerable identity of vegetation, there cannot be a doubt of success in introducing the cultivation of tea, with the strongest probability of all its properties remaining unimpaired.

Under Lord William Bentinck a committee was formed, in 1834, for the purpose of studying the subject, and attempts, partly successful, were made to visit the tea districts of China, in order to collect information, from which sanguine hopes were entertained that in many parts of India tea might be raised in considerable quantity.

3906. *But attention was turned more particularly to this object by the discovery, in 1834, that the tea plant was indigenous in Upper Assam*, a district that had lately been conquered from the Burmese, and which adjoins the Chinese province of Yunnan, where tea is cultivated. Mr. Bruce, Mr. Wallich, and Mr. Griffiths, eminent botanists, were commissioned by the government of India to explore this country, and their report confirmed the accounts that had been given. The tea plant was found growing wild through an extent of thirty or forty miles in Assam, and was used by some of the native tribes. Accordingly, active steps were taken for forming experiments on a considerable scale to cultivate tea in this district; and the result appears to promise ultimate success. The wild tea shrubs flourish in Assam in woods or jungles, where they are protected by the larger trees, and appear to prefer a moist situation. Some of these jungles have been converted into tea plantations, by clearing away much of the trees, and planting branches of the tea shrubs. Some native Chinese have likewise been procured, who are conversant with the manner of gathering and preparing the leaves for use.

Samples of Assam tea have been sent to this country; and having been placed in the hands of several public bodies and private individuals, they have been reported favourably upon; there is, therefore, every prospect that, in the course of time, a considerable supply may be obtained from this source. It does not appear easy at present to compare this tea with that of China, on account of the novelty of the discovery, which will require much experience to render very available. The tea, although evidently the genuine plant, does not appear to correspond exactly with any of the Chinese teas, whether from some slight difference in the cultivation of the shrub, or in the curing of the leaves, but it is said to be most analogous to souchong; of course, the quality must vary, like the teas of China. The specimens yet imported having been considered chiefly as objects of experiment and curiosity, and, consequently, sold at a high price, it is impossible as yet to form an idea of how far this acquisition may render us independent of China; time and much experience will be necessary to solve this problem. In the mean time, the circumstance is highly interesting, particularly since Assam is a hilly country, where the climate is excellent and temperate, and possesses a great variety of beautiful and picturesque situations. Several varieties of the silkworm are likewise found indigenous in it.

3907. *Many attempts have been made by other European nations to cultivate the tea plant* in their colonies with the assistance of Chinese labourers, but hitherto without much profitable result. The difficulty probably does not consist so much in finding a suitable soil and climate as from the high price of human labour, and the great trouble and expense of collecting and preparing the leaves. Tea has been cultivated in Brazil, Carolina, Louisiana, and Rio Janeiro; and the Dutch have grown a good deal in Java.

3908. *The cultivation of the tea plant in England* is perhaps not likely to be attended with any advantage farther than as a matter of curiosity. Both the green and black tea plants have been grown in England. The green tea plants are more hardy than the black in this climate, being kept out in the open air with little protection during the winter, as at Kew, and Messrs. Loddiges, and even as far north as Forfar. The black tea plant is more tender, and is unable to stand unprotected the cold of an English climate. The leaves of the green tea plant grown in England are larger than those of the black tea.

Sect. IX.—Plants employed as substitutes for tea.

3909. *Various plants are employed in different countries as a substitute for the tea-tree of China.* In New Grenada, they use *Alstonia theaformis*, said to be equal to the Chinese tea; in North America, *Gaultheria procumbens* and *Ilex Gongonha*; in Mexico, *Psoralea glandulosa*; in New Holland, *Correa alba*; in Kamtschatka, *Pedicularis lanata*. The leaves of *Lantana macrophylla* are said by Martius to afford an infusion that has exhilarating properties, and which is drunk as an exciting beverage in Brazil.

3910. *Of these, perhaps the most remarkable is the Ilex Paraguensis*, or *tea-tree* of Paraguay, nearly peculiar to that country, and called there *Yerva maté*, the latter term being the name of a particular kind of tea-pot, from the spout of which with a strainer the hot infusion is imbibed. This tree grows wild, and in great abundance in the dense forests in the northern and eastern parts of Paraguay, and is an evergreen about the size of the common orange-tree, the leaf not unlike that of Chinese tea. There is also a better sort, called *caamine*, produced by the Jesuit mission from cultivating the wild sort. When the leaves are gathered, they are dried at the fire, and packed into hide bags containing 200 lbs. each. The use of this beverage appears to have been known to the aboriginal inhabitants, and to have been communicated to the Spaniards. It is not only employed in Paraguay, where it is in universal use, but it is transported to La Plata, Peru, Quito, and Chili; in short, all over the countries in America formerly belonging to Spain, where the inhabitants are passionately fond of it, and drink it at all hours of the day. Some mix sugar with it; others lemon juice; and it is said that five millions of pounds are annually produced in Paraguay. It appears to have a sedative effect, and, like substances of this kind, produces baneful effects, if too much indulged in. Kotzebue states that it is used in Chili alone to the amount of 1,000,000 dollars annually.

3911. Several British plants have been recommended as substitutes for tea, particularly in cases where the Chinese did not agree with the constitution; sage, balm, and mint have been employed. Dr. Withering recommends the leaves of the different species of rose-trees, and of black thorn, which, when dried, he esteems one of the best substitutes for tea that has yet been tried; he observes that the first tender leaves of the whortleberries (*Vaccinium myrtillus*) can scarcely be distinguished from real tea, when properly gathered and dried in the shade. None of these, however, can be said to have all the properties of tea; and they are too imperfectly known to be depended upon.

Sect. X.—Use of tea in different nations.

3912. *This beverage has been used by the Chinese* from time immemorial. In the reign of the Emperor Fitzong, who ascended the throne in the year of Christ 724, or above eleven centuries ago, tea was subjected to a tax, which the Chinese historians inform us was loudly complained of by the people as a grievous oppression, because it fell on a "*necessary of life.*" We have a distinct notice of the use of tea in China by the Arabian travellers Wahat and Abuzaid, who visited that country A.D. 851.

3913. The Chinese drink their tea without milk (which is entirely a European addition), and, in general, without sugar. They throw some tea into a cup, and pour boiling water over it; they cover the cup with a shallow saucer, and let it rest some time. After it has stood sufficiently, they pour the clear liquid into the saucer, and drink it as hot as possible, which is, indeed, their practice with every kind of beverage. The tea used by the Chinese grandees consists of entire leaves, and therefore the extract is perfectly limpid.—*Dr. Mayer's Voyage.*

The Chinese also sometimes beat up the yolk of new-laid eggs with sugar, and mix this with their tea, which is an excellent addition for travellers. They say we suffer the water to remain too long upon the tea, which causes it to extract a bitter portion.

Its use extends to all classes: the mandarin in his palace and the labourer in the field are equally accompanied by the kettle and the tea-pot; and to handle the cups with elegance, and the service of the beverage, forms, as with us, an essential part of female education. The Chinese take it at all times throughout the day as a common beverage, and they likewise introduce it as a refreshment to regale their friends. The tea-pot forms even an important part of the equipage of the traveller, and, for those who have not time nor convenience to prepare their own tea, booths are erected for its preparation and sale on every great road. The higher classes use only the finest teas, and are particularly careful in its preparation; but the lower ranks employ tea often of execrable quality, and even substitute for it the leaves of other plants.

The Japanese, it is said, prepare and drink their tea in the same manner as is done in China; but we have had no accurate information respecting them of late.

3914. *Tea is also used among several other nations of Asia.* The Tonquinese and Cochin-Chinese grow tea, but import the best qualities from China. In Camboja and Siam there is also a considerable consumption of tea imported in Chinese junks, and it has been lately imported into England from the last-named country. The Burmese are also tea consumers; they import it from the neighbouring Chinese province of Yunnan, in parcels of a globular form; but, exclusive of this, the Burmese have a genuine native tea. Tea is also grown in Java, and a good deal of this is imported into Holland.

The natives of Hindostan, Persia, Arabia, and Turkey are not unacquainted with the use of tea, but have recourse to it, for the most part, only for its supposed medicinal virtues. According to the account given by Sir A. Burnes, the Turcomans of Transoxiana and the neighbouring countries are among the greatest consumers of tea. It is conveyed by Chinese caravans through the routes of Yarkand and Badakhshair, and there purchased by Moslem merchants, who forward it to Bokhara.

A singular preparation of tea is in use among the Tartar tribes from the borders of Russia to the Eastern Ocean. Partly for the purpose of rendering tea-leaves more portable and to preserve them, they are moistened with some slightly-glutinous fluid, and then pressed into moulds, from which they take the form of small bricks. To use it, they scrape off a portion of this brick and boil it with butter, flour, milk, and salt; and though we would scarcely anticipate that this preparation would be relished by European palates, some travellers who have tasted it describe it as far from unpleasant. The same tribes use also the infusion in the ordinary way.

3915. *The mode of preparing the infusion of tea in Europe*, or, as it is termed among us, "making tea," is nearly uniform. To make the infusion properly, it is essential that the water, when applied to the tea, should be boiling hot, and, that it should be so, some water is always poured into the tea-pot first, to warm it, and thus prevent it from abstracting heat from the water which is poured upon the tea, and lessening its effect. It is for the same reason that the water should be cooled as little as possible, that a small quantity is first poured upon the tea, and more added afterward for the first infusion. It is well known that the first infusion is the best, containing the chief part of the aroma, and that the second infusion, by adding more water, is less agreeable.

Dr. Kitchener recommends that all the water necessary should be poured in at once, as the second drawing is bad. When much tea is wanted it is best to have two tea-pots instead of two drawings.

Dr. Trusler's method was to make a very strong infusion by pouring boiling water upon the tea, and let it stand twenty minutes, putting into each cup no more than is necessary to fill it about one third full; then each cup was filled with hot water, from an urn or kettle; thus the tea will be always hot and equally strong to the end; and one tea-spoonful will be found enough for three cups for each person; whereas, according to the present mode of making it, a much greater quantity is used. This will be convenient in parties.

Dabuisson's Method.—Put the tea into a kettle with cold water; cover it close; set it on the fire, and make it very nearly, but not quite boil; then take it from the fire; when the leaves sink it is ready.

SECT. XI.—TEA-POTS AND TEA-KETTLES.

3916. *With respect to tea-pots*, the form is of less importance than the material of which they are made. About thirty years ago there was a warm and learned contest respecting the best substance for tea-pots, that is, what they should be made of, to "draw the tea" best. It is obvious that the nature of the material itself will have no particular action upon the tea, and that the question would be decided by determining what substance kept the water hot the longest. It had been supposed, from observation, that metal tea-pots performed the best; and yet the doctrine of the conducting powers of bodies, as understood at that time, appeared to be in favour of earthen-ware, which, being a worse conducter than metal, was supposed to prevent in a greater degree the escape of heat. Each substance, therefore, had its advocates: theory appeared to decide for one, while experience declared for the other. In the mean time, a discovery made by Professor Leslie of Edinburgh threw a new light upon this subject. He found that, although all heated substances throw off invisible rays of radiant heat, yet that the quantity projected depended much more upon the smoothness and roughness of the surface than upon the conducting power of the body; and that *polished* metal, although one of the best conductors of heat, was one of the worst radiators, metal not polished being a good radiator as well as conductor. Although earthen-ware, particularly the black unglazed sort, then so much in use (Wedgwood's), is a bad conductor, yet it is a better radiator than the polished metal, and, consequently, throws off more heat. Water, of course, cools sooner in an earthen-ware tea-pot, particularly if not glazed, than in one of polished metal. Since the date of this discovery, bright metal tea-pots have been considered to be most effectual in preserving the heat of the water; and hence both theory and practice now agree as to the substance best adapted for making a strong infusion of tea.

But for this purpose it is essential that the metal tea-pot shall be *kept bright*; for, if not, it is worse than the earthen-ware, as it is the polish of the surface that particularly acts in preventing the radiant heat from escaping. This principle, though here applied to a tea-pot, has many other important applications, since a bright metal tube of any kind will confine the heat of a fluid better than one covered with cloth, and, therefore, is fittest for conveying steam where it is required not to be given out.

3917. As a set-off against what has just been said, it is to be observed that, if a second quantity of water be poured into the tea-pot, the metal one will give worse tea than the earthen-ware one, because the greater heat of the metal will exhaust the tea at first, so as to leave very little for the second infusion; whereas the inferior temperature of the earthen-ware tea-pot, by extracting only a small proportion at first, leaves some soluble matter for the action of a subsequent infusion.

When the tea-pot is of metal, the handle should be of wood, ivory, or some other bad conductor, to keep it cool for the hand.

3918. *That a tea-pot should pour well*, it is absolutely necessary that either the lid should not fit quite tight, or that a small hole should be made in it. If the lid be quite tight, and there is no perforation, it is obvious that no water can be poured out, since no air can enter to supply its place. This hole is easily concealed by some ornament.

3919. *Tea-kettles* for supplying boiling water for tea have been employed since the first introduction of this beverage, according to the practice of the Chinese. They are made of a variety of forms, sizes, and materials, according to the particular places they are intended for. The largest and strongest for the kitchen are of copper or cast iron (*figs*. 572 and 573); smaller tea-kettles for the same place are made of tin, that is, of tinned sheet iron.

Fig. 572.

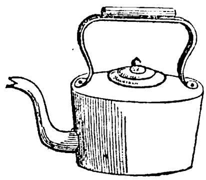

Fig. 573.

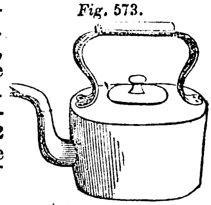


3920. The shoots of tinned plate used for tin tea-kettles are cut out to the proper shape, and are fastened together with a solder that easily melts with the heat of the fire. If such a kettle, *fig*. 574, be put on the fire with a sufficient quantity of water, the solder of the joints would not melt, because this, being a moveable body, carries off the greater part of the heat from the metal, and does not become hot enough for the solder to melt. If, however, the kettle should remain on the fire with very little water, it is evident that the solder which fixes the spout, made also of tin plate, will not be protected; and should the flame be permitted to reach this part, the spout becomes unsoldered, wholly or in part, and the kettle leaks, an accident well known to happen too frequently.

Fig. 574.

The best tin tea-kettles, *fig*. 575, have the spout formed, not of tin plate, but of stout iron tinned, without any seam, and fixed on to the kettle by being passed through a circular hole in the body, to which it is soldered inside, and therefore is safe from the flame: the handles of these are likewise made of stout iron tinned, and fixed on by rivets.

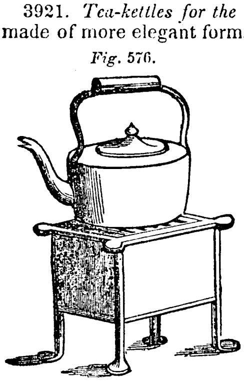
Fig. 575.

The joints of copper tea-kettles are all done with hard solder, which does not melt with the common heat of a fire; this is termed *brazing*.

A small tea-kettle, wholly of tin plate, costs only from 1*s*. to 1*s*. 3*d*., whereas one of the same size with strong spout and handle costs from 3*s*. to 4*s*. With care, the first will last a year or two, but are not fit for the common wear and tear of a kitchen. The *furring* of tea-kettles is a stony deposition from calcareous earth held in solution in the water; though it somewhat impedes the boiling, yet it serves to protect the kettle from rust. In countries where the water contains no dissolved earth, tea-kettles rust and wear out much faster.

3921. *Tea-kettles for the breakfast and tea table* are generally made of more elegant forms, and various contrivances are used to keep the water boiling while it is off the fire.

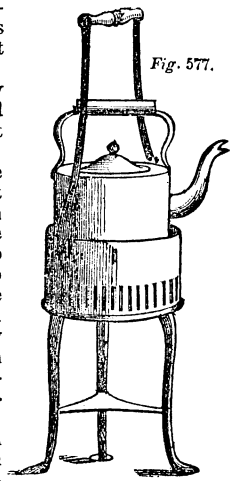
Fig. 576.



An old method of keeping the tea-kettle boiling was, to bring it in upon a chafing-dish filled with lighted charcoal, *fig*. 576. A little grating on it, which was made to raise up to put in the fuel, served to place the tea-kettle upon; but the fumes of the charcoal were found very pernicious, and this gave way to the invention of the tea-urn with an iron heater. The charcoal chafing-dish ought not to be used except in the open air.

Fig. 577 is a tea-kettle placed on a stand that contains a flat iron eater that keeps it boiling. These are usually made of tin-

Fig. 577.



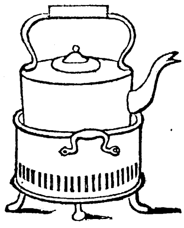


Fig. 578.

plate, and are very economical and convenient. By means of the long handle, the tea-kettle and stand may be carried in together.

3922. *Fig.* 578 is on the same principle, but with short handles.

3923. *Fig.* 579 is a tea-kettle of brass, placed on a stand with a lamp.

3924. In *fig.* 580 the water is kept boiling by iron heaters; *a a* are tubes of copper attached to the tea-kettle, and reaching to the bottom; *b* is one of the tubes detached. Within these are put irons red hot, of which *c* is one separate. The knob on the top of this iron forms the finish to the tube *b*. It is important that the lid of a tea-kettle should not fit so tight as to prevent entirely the escape of steam. When the lid fits perfectly tight, there is

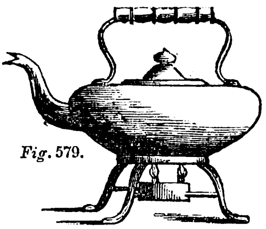

Fig. 579.

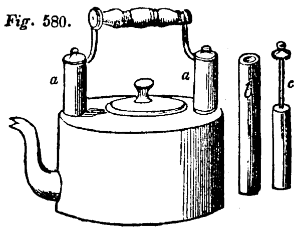
Fig. 580.



danger of the steam forcing the boiling water out suddenly through the spout, by pressing upon the surface of the fluid within, a circumstance which sometimes does occur, and which is very dangerous, particularly where there are children.

3925. *A tea-kettle, fig.* 581, *invented by Count Rumford,* and exhibited at the Royal Institution, has since been lately introduced as a novelty, perhaps without the second inventor knowing that it was not new, although the principle is described in the count's essays. If a common tea-kettle be placed upon an open fire, the heat and flame that rises round the sides has little effect, and it is only that which strikes the bottom that acts considerably in heating the water. By surrounding the body of the tea-kettle with a cylinder, or cone, of sheet iron, *a b*, extending deeper than the bottom of the kettle, and soldered tight round the top, there will, of course, be a cavity between this casing and the kettle. The heat, whether that of a fire or lamp, will not only strike the bottom, but will accumulate to a considerable degree round the sides, and occasion the water to boil much sooner than in the ordinary way. One of the objections to this is the weight of the whole.

Fig. 581.

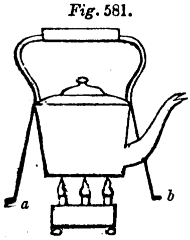


Fig. 582.

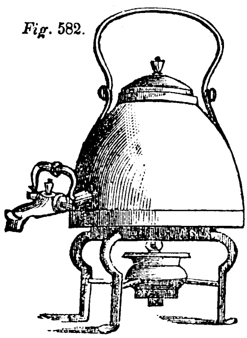
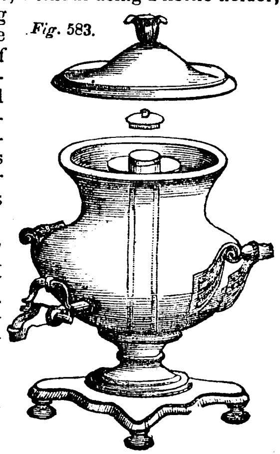


3926. *Fig.* 582, *is a tea-kettle fitted up on the same principle* with a lamp for the table, with a cock like a tea-urn.

3927. The best tea-kettles have handles turned of wood or ivory. One with a metallic handle cannot be touched, when filled with boiling water, without using a kettle-holder, made of some non-conducting substance, as cloth of some kind, or by wrapping a piece of paper round it; while a wooden handle, being itself a bad conductor, may be used without inconvenience. Glass, being a very bad conductor, is now sometimes employed for the thick part of the handles of tea-kettles.

Fig. 583.



3928. *It is said that tea-kettles have lately been made,* which appear to be all of copper, but which are only iron covered by a thin coating of copper by means of the new electrotype process. We mention this particularly, because, if such kettles have been manufactured, they may be offered for sale, and the copper will of course very soon wear off by cleaning.

3929. *The tea-urn* is certainly the most elegant mode of supplying water for tea. It is made in the form of a vase, but in a great varity of patterns. *Fig.* 583 represents one of the usual kind. In the centre there is a vertical tube, into which a cylinder of iron, heated red hot, is slipped down, and covered by a little lid, and that by the cover of the urn. This keeps the water in the urn at a boiling heat. Some tea-urns have lamps below them instead of iron heaters, which have the advantage of keeping the water hot any length of time.

CHAPTER XI.

ON COFFEE.

SECT. I.—HISTORY OF COFFEE.

3930. The introduction of coffee into this country is comparatively of recent date. We are assured by Bruce that the coffee-tree is a native of Abyssinia, and it is said to have been cultivated in that country from time immemorial.

As a general and esteemed beverage, we read of its having been first used in Arabia and Persia, but there are various accounts of its early history. Some say that, having been found useful by some Arabian dervises to keep themselves awake, it was introduced into Persia by a mufti of Aden, from whence it found its way to the principal cities of that kingdom. It was afterward carried into Turkey by Selim on his conquest of Egypt, but it was not until 1554 that it was publicly sold in Constantinople. As the Turks are forbidden the use of wine, it came into great request among them on account of its exhilarating qualities; in consequence of which, numerous coffee-houses were established that were much resorted to, causing great neglect of the mosques. This produced a solemn complaint from the ministers of the Mohammedan religion, and the drinking of coffee was at length prohibited by the mufti. The use of it was, however, again permitted by Solyman the Great, and it was then subjected to a tax, since which time it has been universally employed by the Turks. The Venetians brought it from the Levant in 1615; and, thirty years afterward, some gentlemen, returning from Constantinople to Marseilles, carried home with them this luxury.

3931. *It appears that coffee was first introduced in England by Daniel Edwards, a Turkey merchant,* whose servant, Pasqua, a Greek, understood the manner of roasting it. The servant, under the patronage of Edwards, established the first coffee-house in London, in George Yard, Lombard-street. Coffee was then sold at four or five guineas a pound; and a duty was soon afterward laid upon it of four-pence a gallon, when made into a beverage. Until that time its culture was confined to the East; and it was owing to the Dutch and French that it has been naturalized in South America and the West Indies. Coffee-trees were carried from Mocha to Holland, and so lately as 1714 a coffee-plant was presented to Louis XIV. by the magistrates of Amsterdam, and was placed at Marly under the care of the celebrated Jussieu: a few years afterward, some of the progeny of this plant was conveyed to Cayenne and Martinique, the Dutch having previously introduced it into Surinam. In these tropical regions its cultivation spread rapidly, and all the varieties of it, as the Mocha, the Bourbon, Jamaica, &c., have been the result of various soils, climates, and modes of cultivation. Thus, in the course of two centuries, has a berry, unknown originally as an article of food, except to some savage tribes on the confines of Abyssinia, made its way through the whole of the civilized world. On the Continent, especially in France, coffee is in universal request, and it is now very generally used in Britain. In Mohammedan nations it is drunk twice a day by all ranks, from the sultan to the peasant.

SECT. II.—THE COFFEE-PLANT, AND ITS CULTIVATION.

3932. *The plant that produces coffee* (*Coffea Arabica*) belongs to the natural order of the *Rubiaceæ*, and cannot be grown to advantage in countries where the thermometer descends at any time below 55°. The tree grows to the height of twelve or fifteen feet, with leaves not unlike those of the common laurel, although more pointed, and not so dry and thick, *fig.* 584. The blossoms are white, much like those of jasmine, and issue from the angles of the leaf-stalks. When the flowers fade, they are succeeded by the coffee-bean, or seed, which is enclosed in a berry of a red colour when ripe, resembling a cherry. Each berry contains two oval seeds, or beans, which are surrounded by a yellowish glutinous pulp. These seeds, constituting the coffee of commerce, have one side convex, and the other flat, with a little straight furrow, as we see in the common coffee-bean; they are placed with the flat sides together, and are covered by a tough membrane, called the *parchment.* The trees are raised from seed, and are afterward planted out at regular distances. They flourish best, and produce berries smaller and of a finer flavour, in light, dry soils than in those which are rich and moist, although in the latter they grow to a large size, and give a greater quantity of

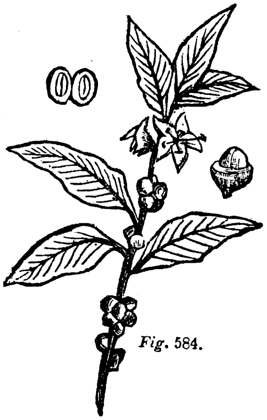


Fig. 584.

coffee. They begin bearing when they are two years old; and the aspect of a coffee plantation is very interesting during the time of flowering. In a single night the blossoms expand in such profusion as to resemble the effects of a snow-storm, but do not last longer than a very few days. The berries are known to be ripe when they assume a dark-red colour, and will drop from the trees if not gathered immediately. The Arabians suffer them to fall upon cloths placed for their reception; but in the West Indies the negroes are set to gather them.

3933. *To prepare the coffee-beans*, the berries are exposed to the sun for a few days, that the pulp may ferment and throw off a strong acidulous moisture. They are then gradually dried for about three weeks, and put into a mill to separate the husks from the seed. Some omit the fermentation, and separate the husks as soon as the seeds are gathered, by passing them under heavy rollers. The parchment is taken off by another mill, and after being winnowed to separate the chaff, the seeds, when quite dry, are ready. It is thought by some that the flavour of the coffee would be better preserved if it were sent home not divested of its coverings; in the West Indies they keep it in this manner, and beat it out only as it is wanted.

3934. *The best coffee is the Arabian;* this is most extensively cultivated in the province of Yemen, and chiefly in the districts of Aden and Mocha, whence the name of our Mocha coffee. This superiority is attributed partly to the difference of soil and climate, and partly to culture. Although Arabia is very hot in the plains, it possesses mountains where the air is mild, and the coffee is raised upon their slopes in a soil that is rocky and dry, but so situated as to admit of irrigation; though the berries are small, they have seeds of a very delicate flavour. In our colonies, coffee is planted in a richer soil, by which the berries are of larger size, but are comparatively insipid. In a deep, rich soil each tree will yield from twelve to sixteen ounces of coffee; but upon a soil the most favourable for the best kind, it will not yield above half that weight. In Arabia, where the climate is drier, they also cure the berry in a different mode.

Mocha coffee may be known by its having a smaller and rounder bean than any other, and likewise a more agreeable smell and taste.

3935. *Next in reputation and quality is the Java and Ceylon coffee*, and then the coffees of Bourbon and Martinique; also that of Berbice, a district of the colony of British Guiana. The Jamaica and St. Domingo coffees are less esteemed; the two extremities of the beans from these are pointed.

SECT. III.—ANALYSIS OF COFFEE.

3936. *Coffee has been analyzed by various chemists*, but the results of their analyses are far from being uniform. Raw coffee contains a yellowish-brown transparent extract, to which the name of *Caffeine* has been given, and which constitutes the characteristic portion of coffee; coffee contains also a resinous matter, an oil or fatty substance, an aromatic principle, and some tannin and gallic acid. Six pounds of coffee give ninety grains of caffeine, a proximate principle remarkable for containing 21·54 per cent. of nitrogen, which is a larger quantity than is found in most other vegetables; it is a crystallizable salt of a bitter taste, producing an exhilarating effect when taken in four or five grains, such as is felt when good coffee is drunk. It was first discovered by Runge in 1820, and it is considered by Liebig as nearly identical, if not quite so, with *Theine*, a principle existing in tea. See "Tea."

SECT. IV.—ROASTING AND GRINDING COFFEE.

3937. It appears that a considerable change takes place in the arrangement of the constituents of coffee by the application of heat in roasting it. Independently of one of the objects of roasting, namely, that of destroying its toughness, and rendering it easily ground, its tannin and other principles are rendered partly soluble in water; and it is to the tannin that the brown colour of the decoction of coffee is owing. An aromatic flavour is likewise developed during torrefaction, which is not perceived in the raw berry, and which is not produced in the greatest perfection until the heat has arrived at a certain degree of temperature; but if the heat be increased beyond this, the flavour is again dissipated, and little remains but a bitter and astringent matter with carbon.

3938. *The roasting of coffee in the best manner requires great nicety*, and much of the qualities of the beverage depends upon the operation. It is essential that the process should be performed in a close vessel, otherwise much of the fine aroma will be dissipated in the air. It is usually roasted in a hollow cylinder made of sheet-iron, which is kept turning over a brisk fire, to prevent any part from being more heated than another; and when the coffee has acquired a deep cinnamon colour, and an oily appearance, and the peculiar fragrance of roasted coffee is perceived to be sufficiently strong, it should be taken from the fire, well shaken, and suffered to cool. Not more than half a pound of coffee should be roasted at once for domestic use; for if the quantity is greater, it becomes impossible to regulate the heat in such a manner as to secure a good result. If the heat be so violent as to burn any part, the whole will be materially injured

Fig. 585 represents a very simple coffee-roaster, being merely a cylinder with a sliding door, turned over a charcoal fire made in the receptacle beneath, with a cover to shut close, and a tube to carry off the fumes of the charcoal. *Fig.* 586 is another, of a form a little different.

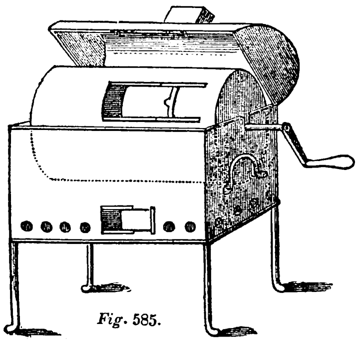

Fig. 585.

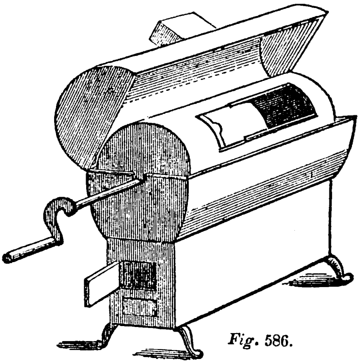

Fig. 586.

The coffee-roaster should never be filled above one third; for, by roasting, the bulk of coffee is nearly doubled, and sufficient space ought to remain to allow of turning the coffee readily, that every part may be equally exposed to the heat. Sometimes a similar cylinder of sheet-iron is used, but fastened to a spit that is turned by a jack.

3939. In Italy they roast coffee in small quantities very frequently in one of the thin flasks of glass used for oil, which answer extremely well if the roasting is performed over a charcoal fire, and the coffee shaken and turned often The non-conducting power of the glass is thought to give this material an advantage over metal, as being less liable to burn; added to which the progress of the roasting can be better watched. One of these flasks will roast somewhat less than a quarter of a pound at a time; and it is, perhaps, worth while mentioning that this mode is often found useful to the traveller.

It is desirable, in the commencement of the roasting, that the steam should escape as quickly as possible; and Mr. Donovan recommends that, instead of roasting the coffee in an atmosphere of its own steam, as is usually done, it should first be dried on an iron pan over a very gentle fire, keeping it constantly stirring so as to present new surfaces, until the colour becomes yellow. In this way the chief part of the water will be dissipated without exerting any detrimental influence on the substance which is afterward to form the aromatic bitter. After being thus dried, the coffee should be pounded into coarse fragments, by no means too fine; each kernel, as it occurs, being divided, perhaps, into four or five parts. In this state it is to be transferred into the roasting apparatus, and scorched to the proper degree. It is observed that when coffee is roasted in the usual way, without being broken, a portion often remains in the centre of the beans not sufficiently done.

3940. *The roasting of coffee for the dealers in London and Paris* is now become a separate branch of business, and some of the roasters perform the operation on a great scale with considerable skill; they are guided in the process by the tint of brown produced, and the proper aroma, which is prevented by means of their apparatus from escaping. When coffee can be had ready roasted from dealers who roast and grind every day, much trouble may be saved in a family that is not anxious to have the very best; but the retailers, says Mr. Donovan, almost invariably roast their coffee too little; the more it is roasted, the greater is the loss of weight on it, and the less their profit is at a given price; and the more of it, within certain restrictions, will be consumed to produce a given flavour. Coffee loses from twenty to thirty per cent. by sufficient roasting; but if the deficiency exceed that, it is injured. Mr. Donovan is inclined to attribute much of the vapid, raw, and poor taste of our coffee, so much complained of by foreigners, to insufficient roasting. It should be observed, however, that if coffee be roasted too much it becomes too bitter, with little flavour. It is found by experience that the qualities of the beverage depend as much upon judicious roasting as upon the variety of the raw coffee purchased.

3941. *The grinding of coffee* is performed by iron mills. A very small portable mill is common, which is useful on occasion, but too tedious for a large family, as it holds so small a quantity. The portable coffee-mill consists of a square box, either of mahogany or iron, japanned, containing in the interior a hollow cone of steel, with sharp grooves on the inside; into this fits a conical piece of hardened iron or steel, having spiral grooves cut upon its surface, and capable of being turned round by a handle. The coffee is put into a hopper, which conducts it into the hollow cone, where it is crushed by the motion of the solid cone as it revolves. The powder ground in this manner falls into a drawer below.

3942. When large quantities are wanted in a family, a coffee-mill of a larger kind, requiring less labour, is fixed against the wall; but the construction of the mill is gen erally the same. This is a necessary machine in every family, as the goodness of the coffee depends much upon its being fresh ground, which can only be ensured by grinding it at home. Coffee ought to be ground fine, in order that the water may be enabled to penetrate to the centre of the particles, and extract those parts upon which the valuable qualities of the beverage depend. It is not, in general, ground fine enough. When coffee is very highly roasted, so as to develop the greatest quantity of bitter aroma without burning, it is rendered more difficult to grind, for it then acquires an oily surface, which causes the kernels to slip over each other, and hence they are not caught so readily by the teeth of the mill; but the powder, when obtained, is finer than if the coffee had been less roasted, because it is rendered more friable.

Sect. V.—Preserving Coffee.

3943. *Roasted coffee loses much of its flavour by exposure to the air;* on the other hand, it is said, that while raw it not only does not lose its flavour for a year or two, but improves by keeping. That the fine aromatic flavour of good coffee, and which is one of its chief recommendations, depends upon some principle that is extremely volatile, a little observation will render evident. If a cup of the best coffee be placed upon a table boiling hot, it will fill the room with its fragrance; but the coffee, when warmed again after being cold, will be found to have lost most of its flavour. The fragrance diffused through the air is a sure indication in what manner it was dissipated; and therefore it is evident that in preparing coffee every possible endeavour should be made to preserve this precious part of the beverage. To have coffee in perfection, it should be roasted and ground just before it is to be used, and more should not be ground at a time than is wanted for immediate use; or, if it be necessary to grind more, it should be kept close from the air.

3944. *Count Rumford's apparatus for preserving the aromatic fragrance of ground coffee* may sometimes be useful. It consisted of a cylindrical box made of strong tin, four and a half inches in diameter, and five inches in height, formed as accurately as possible within, to which a piston is so adapted as to close it very exactly, and when pressed down into it, to remain in the place where it is left, without being in danger of being pushed upward by the elasticity of the ground coffee which it is destined to confine. This piston was composed of a circular plate of very stout tin, which was soldered to the lower part of an elastic hoop of tin, about two inches wide, which was made to fit into the cylindrical box as exactly as possible, and so as not to be moved up and down without employing some considerable force. This hoop was rendered elastic by means of a number of vertical slits made in the sides of it; on the upper side of the circular plate of tin, which closed this hoop below, and in the centre of it, there was fixed a strong ring, of about one inch in diameter, which served instead of a piston rod, or handle for the piston. The cylindrical box was closed above by a cover, which was fitted to it with care, in order that the air which was shut up within the box, between the piston and the cover, might be well confined.

We may observe that a wide-mouthed glass bottle will answer tolerably well, if a good cork, having a piece of gold-beater's skin, or leaf India rubber, on the lower side, be well fitted into the neck; or the lower part of the cork may be covered with wax.

3945. *Coffee readily imbibes exhalations from other substances*, and thus often acquires a bad flavour; brown sugar placed near it will communicate a disagreeable flavour. It is stated that the coffee in the West Indies has often been injured by being laid in rooms near the sugar works, or where rum is distilled; and the same effect has been produced by bringing over coffee in the same ships with rum and sugar. Dr. Moseley mentions that a few bags of pepper on board a ship from India spoiled a whole cargo of coffee.

Sect. VI.—Preparing Beverages from Coffee.

3946. *The best method of preparing a beverage from coffee*, or, as it is termed, *making coffee*, is a subject that has received a good deal of attention, even from persons eminent for their scientific acquirements; among them we may mention particularly Count Rumford, and, lately, Mr. Donovan.

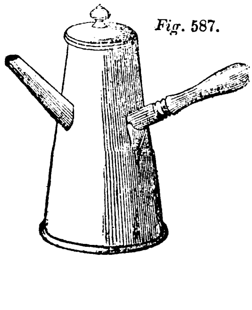

Fig. 587.

3947. *The most usual method of making coffee in England* is the following: Put fresh-ground coffee into a coffee-pot, *fig.* 587, with a sufficient quantity of water, and set this on the fire till it boils for a minute or two; then remove it from the fire, pour out a cupful, which is to be returned into the coffee-pot to throw down the grounds that may be floating: repeat this, and let the coffee-pot stand near the fire, but not on too hot a place, until the grounds have subsided to the bottom; in a few minutes the coffee will be clear without any other preparation, and may be poured into cups: in this manner, with good materials in sufficient quantity, and proper care, excellent coffee may be made. The most valuable part of the coffee is soon extracted, and it is certain that long boiling dissipates the fine aroma and flavour. Some make it a rule not to suffer the coffee to boil, but only to bring it just to the boiling point; but it is said by Mr. Donovan that it requires boiling for a little time to extract the whole of the bitter, in which, he conceives, much of the exhilarating qualities of the coffee reside. As an improvement on the common mode, he therefore recommends that the whole of the water should be divided into two parts; one half should be put on the fire with the coffee, and as soon as the liquor boils it should be taken off the fire, allowed to subside for a few seconds, and then poured off as clear as it will run. Immediately, the remaining half of the water, at a boiling heat, is to be poured on the grounds, the coffee-pot is to be placed on the fire, and kept boiling three minutes. This will extract all the bitterness left on the grounds; and after a few moments' subsidence, the clear part is to be poured off and mixed with the former liquor. This mixed liquor now contains all the qualities, both aroma and bitter, which originally existed in the roasted coffee, and is as hot as any taste could desire it. From what has been said, the error of some persons is evident, who suppose that long boiling is necessary to extract the strength of coffee.

3948. *The usual method of preparing coffee in France*, as described by the French naturalist Du Tour, is the following: Let the powder be poured into the coffee-pot filled with boiling water, in the proportion of two ounces and a half to two pounds, or two English pints of water. Let the mixture be stirred with a spoon, and the coffee-pot be soon taken off the fire, but suffered to remain closely shut, for about at least two hours, on the warm ashes of a wood fire. During the infusion the liquor should be several times agitated by a chocolate frother, or something of the same kind, and be finally left for about a quarter of an hour to settle. This long, very gentle simmering over hot ashes is probably favourable, but it would require some care to effect it where coal is the fuel.

3949. *The Café noir* of the French is coffee made strong with water only. *Café au lait* must not be made by boiling coffee and milk together, as milk is not proper to extract the coffee; the coffee must first be made as café noir, only stronger; as much of this coffee is poured in the cup as is required, and the cup is then filled up with *boiled* milk. *Café à la crême* is made by adding boiled cream to strong clear coffee, and heating them together.

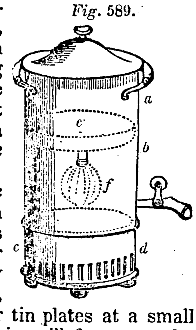
3950. *The clearing of coffee* is a circumstance demanding particular attention. After the heaviest parts of the grounds have settled, there are still fine particles suspended for some time, and if the coffee be poured off before these have subsided, the liquor is deficient in that transparency which is one test of its perfection; for coffee not well cleared has always an unpleasant bitter taste. In general, the coffee becomes clear by simply remaining quiet for a few minutes, as we have stated; but those who are anxious to have it as clear as possible employ some artificial means of assisting the clearing. The addition of a little isinglass, hartshorn shavings, skins of eels or soles, white of eggs, &c., has been recommended for clearing; but it is evident that these substances, to produce their effect, which is upon the same principle as the fining of beer or wine, should be dissolved previously, for if put in without, it would require so much time to dissolve, that the flavour of the coffee would vanish.

3951. *The white of egg clears well*, but often passes into the coffee-cups, when the coffee is poured out, in the form of little shreds, consisting of the coagulated egg; the coffee in that case should be strained. Mr. Donovan recommends drying white of egg by spreading it thin upon a plate before a brisk fire for twelve or fourteen hours. This dried egg will easily scale off the plate, and may be kept for any length of time in a bottle corked. A small bit of the size of a sixpence will be sufficient to clear three ounces of coffee. All that is necessary is to throw it into the half of the coffee made to boil as in the above directions, by which it will be dissolved, and when this half is added to the other that had been already poured off, the clearing will be effected on resting a few minutes; or this dried white of egg may be previously dissolved in a table-spoonful of boiling water, and added to the coffee before it is set down to settle.

3952. *The difficulty of clearing coffee has led to the invention of a variety of apparatus for coffee-making.* One of the simplest modes is putting the coffee into a bag of muslin suspended to the rim of the coffee-pot, *fig.* 588; and, by pouring boiling water through it, the soluble parts of the coffee are separated, and the grounds thoroughly retained, the bag serving as a filter. The objection to this method is, that the water, remaining but a very short time in contact with the coffee, cannot extract from it the whole that is required. Any coffee-pot with such a bag fitted into its mouth is termed a *coffee biggin*.

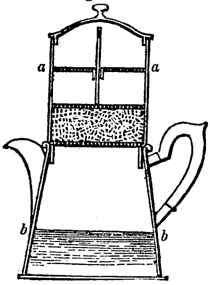
Fig. 588.

Fig. 589.



3953. *Evans's apparatus for making coffee* is intended to let the coffee soak longer in the water, and thus extract more of its principles. *a b*, *fig.* 589, is a tin cylinder with handles and a cover, which is nearly filled with water, and placed upon a stand, *c d*, containing a lamp. *e* is a low cylinder made of two circular tin plates at a small distance apart, and closed all round; this, being filled only with air, will float upon the water, and will bear to have the bag with the coffee, *f*, suspended to it beneath in the water; after the latter has boiled long enough, the decoction of the coffee will mix with

Fig. 590.



the water, but perfectly fine, and may be drawn fit for use by the stop-cock.

3954. *Count Rumford's percolator* is an improvement upon this, and is in very general use under the name of *coffee filterer. a a, fig.* 590, is a cylindrical vessel of metal of any kind, silver or tin japanned on the outside; this vessel fits into another, *b b*, in the form of a tea-pot or any other. The cylindrical vessel has a bottom that is perforated with numerous very small holes, and into this, the lid being taken off, the coffee is put, resting on the perforated bottom. To press the coffee as compactly as possible, that the water may not penetrate so quickly as in the bag, a cylindrical plate of metal, also perforated, is forced down, guided by a metal stem; and this stem passes through another perforated plate at top, to keep it steady. The coffee being packed close, by pressing the stem down hard several times, water is poured upon the uppermost perforated plate, and it passes through the perforations to the coffee, through which it makes its way slowly, dissolving the soluble part, which descends very slowly into the lower vessel, *b b*. This infusion of the coffee, which may now be pourèd out, is perfectly transparent, and the whole of the aroma is preserved. There are two objections to this apparatus in its original form. It does not entirely exhaust the coffee of its virtues; and, consequently, as it requires a greater quantity of coffee than the common method, it is not the most economical, although a very convenient and elegant mode. But the greatest objection is that, if there be much thickness of coffee, or if it be pressed very hard, the liquid requires so much time to percolate, that it is too much cooled before it can be poured out. This last objection is removed by placing the percolator over a spirit lamp, as in *fig.* 591, or it may be placed on a small vessel containing an iron heated; but care must be taken to have some method of fixing securely the percolator to this stand, after the heater is put into it, that the latter may not drop off in carrying. For this purpose, there should be handles to the percolator; and in this form, or with a lamp, it is at present much used, and is, perhaps, upon the whole, the best apparatus for the table, when a small quantity of coffee only is wanted.

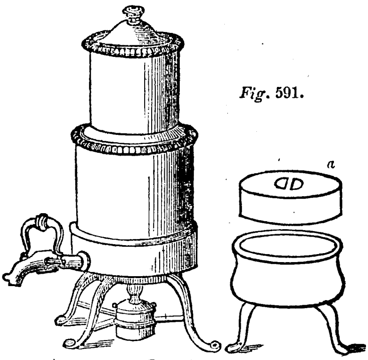


Fig. 591.

3955. *When much coffee is required* for parties, the way is to make and clear it in the kitchen, and send it up in a *coffee urn with a* lamp, *fig.* 592.

Fig. 592.

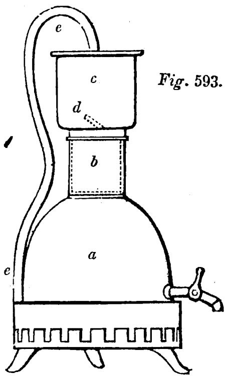

Fig. 593.

3956. *Mr. Jones, of the Strand, London, has an apparatus* for making coffee: *a, fig.* 593, is a vessel placed over a lamp, into which the proper quantity of water is put; *b* is a double vessel, the internal one consisting of a perforated metal cup, to hold the ground coffee; *c* is another vessel fitting on *b*, and having a valve at *d*. When the water in *a* boils, the steam ascends among the coffee in *b*; and when it accumulates in sufficient force, its pressure upon the surface of the water in *a* causes the boiling fluid to rise in the pipe *e e*, and to be discharged in the vessel *c*; the lamp may then be blown out, and the liquid will percolate through the coffee in *b*, and passing through the perforated strainer, will descend into a filtered infusion.

3957. *Parker's patent steam-fountain coffee-maker* is a machine by which the extract of coffee is prepared in a very easy and expeditious manner. When the extract is made, it may be diluted with boiling water to suit the palate; or hot milk may be used instead of water, making *café au lait.*

Fig. 594.

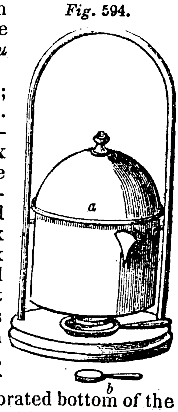

Fig. 594 represents the external appearance of the apparatus; and *fig.* 595 is a section to show its construction and mode of action. *a* is a box of metal to hold the coffee, having its bottom lid perforated with numerous small holes. From the lower part of this box proceeds a funnel, *b*, that reaches nearly to the bottom of an outside vessel or cylinder of metal, *c d*, which is divided into two parts interiorly by a partition, *k k*; and on the middle of this partition is fixed a tube, into which the neck of the funnel is put, and on which the box with the coffee rests. This exterior vessel is covered by a convex lid, *e*. The whole is placed over a spirit lamp, *f*, and is suspended by centres fixed to the upright arched rod, *g g h*. Having taken out the box with its funnel, it is filled with coffee, and boiling water is poured down the tube in the interior; this will pass into the division at the lower part, *c d*; then the box with the coffee is to be replaced, and the lamp lighted. The steam which is formed forces the water in *c d* to rise through the tube *b*, and passes upward through the perforated bottom of the box into the coffee, forming the extract, which is seen rising as a dark fluid through the perforated lid of *a*, and flowing over into the upper division, *l l*. The passage of the water should be permitted to continue till it becomes pale-coloured, and has consequently extracted all the goodness of the coffee, when the lamp should be extinguished, and the lid put on. To get out the extract, the finger is pressed upon the little wooden cup at *a*, *fig.* 594, by which the cylindrical vessel is brought into a horizontal position, and the extract is poured out through the spout. After making the extract, it is best not to drain off the liquid remaining within the rim of the cover, but to let it return into the boiler, which it will do as soon as the lamp is extinguished; thus any sediment will return with it.

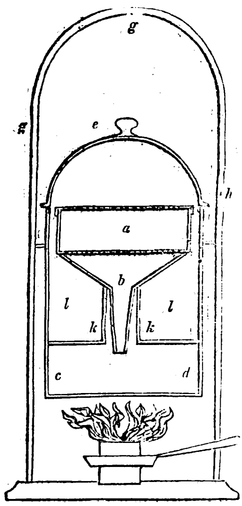
Fig. 595.



The filling of the box is best done by piling up the ground coffee in the centre, and then striking it off with a knife, as is done with corn in a bushel measure. The time for making the extract of coffee, where hot water is used, should never exceed five minutes. If it takes longer, it can arise only from the coffee being ground too finely; and this not only increases the expenditure of spirits of wine and of time, but likewise injures the quality of the extract. The remedy is to grind the coffee coarser and coarser until the operation, after the water in the boiler boils, lasts only three minutes. Instead of the ordinary spirit-lamp with a wick, a little cup of tin with a handle is used; this is filled two thirds with just as much spirit of wine as is necessary for one operation, by which the waste very common in lamps with wicks is avoided. Care should be taken not to spill any of the spirit on the outside of the cup, or it will blaze, and occasion inconvenience. An ordinary spirit-lamp with a wick will answer sufficiently well. *b*, *fig.* 594, is an extinguisher with a handle, to put out the lamp with. A variety of this machine is likewise made to use by means of a fire instead of a lamp. The extract of coffee prepared by this apparatus contains all the aroma and other fine qualities of the coffee.

Fig. 596.

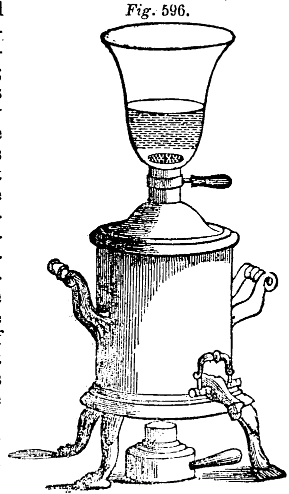


Fig. 597.

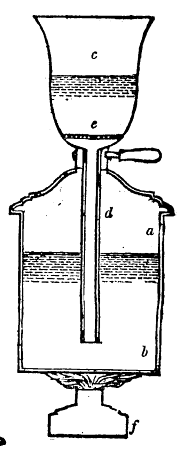
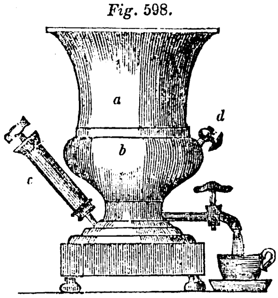


3958. *Fig.* 596 *is a view of Platow's patent filterer* for making coffee; and *fig.* 597 is a section of the same. The lowest vessel, *a b*, is often japanned, into which water is put, proportioned to the coffee to be used. *c* is a glass vase with a tin tube, *d*, attached, and having a little circular plate, *e*, fixed at the bottom of the glass, and pierced full of very fine holes. The glass vase and tube are fitted on the top of *a b*, the tube going into the water and near to the bottom. The coffee is put into the glass vase without water. The lamp, *f*, being applied to the bottom of the lower vessel, the water in it is caused to boil, and as soon as the steam forms it presses upon the surface of the water and forces it up through the tube into the coffee in the vase; and when enough has been so raised the lamp is withdrawn, which stops the formation of steam, otherwise the water would be forced over the top of the vase. As the water now cools a little, the stream will be condensed and no longer keep up the water, which will therefore descend by its own weight into the vessel *a b*, carrying with it the extract of the coffee. The made coffee is then drawn off into cups by the stop-cock, represented in *fig.* 596.

3959. *By Brain's vacuum, or pneumatic filter*, *fig.* 598, coffee may be made perfectly clear and bright in a few minutes: *a* is a receptacle made of tin, Britannia metal, or other material, fitting into another one, *b*, which has an exhausting piston, *c*, attached, by which it may be exhausted of air. The top of the vessel, *b*, is covered with a wire grating, and before the vessel *a* is placed on it, a piece of close muslin, linen, or shamoy leather is laid over the grating, and the vessel *a* is forced down, so that the joint is air-tight. The coffee is put into the vessel or chamber *a*, which is open at the top; then open the little plug, *d*, and press the piston down to the bottom, and add as much boiling water over the coffee as is necessary. Now shut the plug, *d*, work the exhausting pump, *c*, and draw the air out of the vessel *b*, so as to produce a vacuum in it; when that is effected, the pressure of the atmosphere, acting upon the liquid in *a*, will force it through the coffee and the filter down into *b*, from whence it may be drawn perfectly clear into cups. This machine not only produces coffee beautifully clear, but also with great expedition. The closer the muslin or linen, the more perfect will be the filtration. Previous to using the apparatus, it should be warmed by passing hot water through it. It is to be observed that this apparatus, from its mode of operation, is not proper to be put upon the table, but is intended for preparing the coffee in the kitchen, whence it must be transferred to a more sightly vessel.

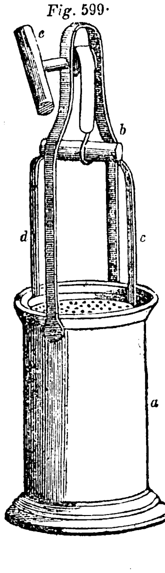
Fig. 598.



3960. *Palmer's pneumatic filtering* machine is nearly of the same construction. The *essence of coffee* may be also thus prepared by this apparatus. Put four ounces of the best ground coffee into a covered vessel, with twelve ounces of cold soft water. Let it stand for twenty-four hours, stirring it two or three times; after which, pour into the pneumatic filtering machine, and pass the liquid two or three times through it. The same apparatus will do also to filter wine, water, or other fluids.

3961. *Beart's coffee percolator* acts also by producing a vacuum below the coffee, in consequence of which the liquid is forced through by the pressure of the atmosphere. *a*, *fig.* 599, is a cylindrical vessel of strong tin or other metal, having a piston that fits the inside, and is made tight by a piece of soft leather; the bottom of this piston is pierced with fine holes, and on this the coffee is put. This piston is raised up by means of a handle fixed to two uprights, *c* and *d*. If now this piston be put down to the bottom of the vessel *a*, and the coffee and water be put into the vessel on the piston, in drawing the piston up by the handle, all the air in *a* will be brought with it, except what forces through the coffee and percolator to fill up the vacuum that would be formed. Hence a clear and transparent extract of the coffee will be produced, which will be strong in proportion to the water employed. As considerable force is necessary to raise the piston, an axis, *c*, is passed through another upright piece bent at top like an arch, and round this axis a band passes that is attached to the handle *b* by a hook; this axis being turned by a lever or cross handle, the raising of the piston is easily effected. The facility and quickness with which coffee can be made perfectly clear by this apparatus is a great recommendation; but it is evident that, though the principle is unobjectionable, the form does not render it suitable to the drawing-room.

Fig. 599.



3962. *An essence of coffee* may be purchased in the shops, which will supply a cup of coffee at any time by diluting it with water; but as the mode of preparing it is not generally known, and the taste is somewhat peculiar, we cannot recommend it as equal to the usual coffee, though it may be convenient, and even useful, on par ticular occasions, as in travelling. A tea-spoonful put into a cup of boiling water makes one of coffee.

3963. *Coffee may be prepared by simmering over a lamp* in the following manner, which may be useful for those who wish for an early cup of coffee without disturbing servants Procure for the purpose a simple cylindrical coffee-pot of tin, *a. fig.* 600, as wide at top as bottom, to hold the coffee and water; then another cylinder, *b c*, must surround it, open at bottom, *d e*, and joined to the inner one at top, so much larger as to leave an inch space, or half an inch between the two, and reaching an inch below the bottom of the inside one. To this outside cylinder three short feet, *f g*, of strong wire may be fixed. The cover of the pot should be double, the better to confine the heat; a handle is fixed to the outside cylinder, and also a spout from the inside one of sufficient length. Below this cylinder, which contains the coffee and the water, a small lamp with three wicks, or a chemical Argand lamp, is placed between the wire legs. The space between the two cylinders being always full of hot air, which is allowed to issue through holes at *h i*. The lamp should be so regulated that the coffee should not boil, but only simmer; and a very small lamp will be sufficient to keep up the simmering for any length of time. The oil should be of the best kind; but spirit of wine or naphtha will be better to prevent smoke or smell. Before the coffee is drunk, the lamp should be withdrawn, and the liquor should rest to be cleared.

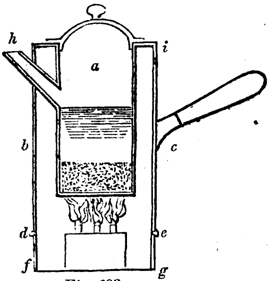


Fig. 600.

3964. *Fig.* 601 is an apparatus for making coffee *very useful for travellers.* It consists of a tin cylindrical vessel, with an opening for introducing a lamp with three wicks, which may burn spirits of wine. Three wires bent at both ends, as in the wood-cut, are hung upon the edge of the cylinder, and upon these the coffee-pot is made to rest. As the handle is made to take off, the coffee-pot can be packed inside the cylinder.

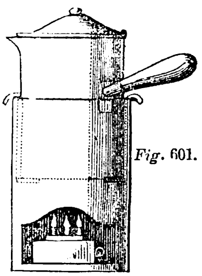

Fig. 601.

3965. *Coffee may likewise be made by infusing a proper quantity in cold water*, and letting it remain all night; in the morning the infusion may be filtered, and only heated, not boiled; some prefer this mode.

3966. *Professor Gregory has given a receipt for preparing a cold infusion of coffee.* He directs that a cylinder shall be provided about two feet long and two inches wide, terminating below in a funnel, which is to be placed in the neck of a bottle. A small portion of cotton wool being inserted in the neck of the funnel, half a pound of coffee is to be mixed with as much water as to form the consistence of thin porridge; and when this has stood an hour or two, it is to be introduced into the cylinder. Immediately a very strong infusion will begin to drop into the bottle; and when the dropping ceases, the coffee will still be impregnated with strong liquor. To obtain this, more water must be poured upon the coffee, till the infusion becomes pale, when the coffee is exhausted. Several bottles will be required, and this operation may last three or four days, some kinds of coffee being sooner exhausted than others. The contents of the several bottles are to be mixed together; and in this way six imperial pints of good coffee may be obtained from half a pound; but the strength, of course, is a matter of taste. The coffee exhausted in this manner will still yield some weak infusion. When heated, this coffee should not be suffered to boil. It is evident that the length of the tube assists the percolation by the hydrostatic pressure.

3967. *With respect to the quantity of coffee used in making the decoction*, much depends upon the taste of the consumer. The general use of tea among us, and the greater price of coffee while the high duty existed, occasioned the latter to be much less used in England, and the art of preparing it less understood than on the Continent. The greatest and most common fault in English coffee is the too small quantity of the ingredient; and coffee is usually made stronger on the other side of the Channel than it is here. The present cheapness of our coffee, however, renders the quantity less an object of economy than it was formerly. Count Rumford, who had a very favourable opinion of the valuable qualities of coffee, observes, that to make it good, such as is usually drunk after dinner, a pound of good Mocha coffee, which, when roasted and ground, weighs only thirteen ounces, serves to make fifty-six full cups, or a little less than a quarter of an ounce to a coffee-cup of moderate size. Mr. Donovan gives the proportion of two ounces and a half of well-roasted coffee to an imperial quart measure of water. Some may prefer it rather weaker. If coffee is too strong, the fine aromatic flavour is less perceived than the bitter.

3968. *The method of making coffee in some parts of Turkey* is thus described by Mr. Fellows in his "Excursions through Asia Minor:" "Each cup is made separately, the little sauce-pan, or ladle, in which it is prepared being about an inch wide and two deep; this is more than half filled with coffee, finely pounded with a pestle and mortar, and then filled up with water; after being placed for a few seconds on the fire, the contents are poured, or, rather, shaken out (being much thicker than chocolate), without the addition of cream or sugar, into a china cup of the size and shape of half an egg-shell, which is enclosed in one of ornamented metal for convenience of holding in the hand."

3969. *Coffee is always drunk without milk* in Turkey and the East, and also in France and England *after dinner*. When taken at breakfast with us, milk, or, what is much better, cream, is added to it. The milk should always be first boiled; and when the quantity of the boiled milk equals that of the strong-made coffee, the beverage is termed by the French *café au lait*.

3970. *From what has been stated, it appears that, to make good coffee, the following circumstances are to be attended to:* procure coffee of good quality; have it carefully roasted and ground, if possible, on the day it is wanted; use a sufficient quantity in making the decoction; boil it according to the directions given above; clarify it well; add to it cream or boiled milk; let it be served quite hot.

3971. *Coffee is sometimes adulterated* by mixing with roasted pease and beans, but, most of all, with *chiccory;* and many grocers have been prosecuted and convicted of this fraud.

But, as it is impossible to counterfeit the berry in the unground state, the best precaution is never to purchase ground coffee, but to see it ground; or, what is better, to roast and grind it at home. The poor are most liable to suffer by this species of dishonesty, as they generally purchase coffee ready ground in very small quantities. To detect the adulteration of coffee by pease and beans is beyond the reach of chemical science.

Sect. VII.—Substitutes for Coffee.

Various substitutes for coffee have been tried and recommended; but none of these are found to have much of the flavour of true coffee; and considering the trouble attending on such preparations, and the present low price of the real article, it is much to be doubted whether any of them be worth using; certain it is, that no substance is brought forward that can be at all compared, in point of flavour and other properties, to coffee.

3972. *Chiccory* is used in many places on the Continent as a substitute for coffee, and is also mixed with it, either from an idea of improving its flavour, or for economy. For a description of the plant, see Book VII., Chap. VII., Sect. VIII.

The roots, cut in pieces, kiln-dried, and ground, are used by the poorer classes in these countries. The powder has a strong resemblance to coffee; but, instead of the flavour of that berry, it has rather an odour of liquorice, and seems to have little in common with coffee except its colour. This preparation does not appear to be much used in England, except for adulterating coffee; and as large quantities have been imported, it is difficult to say to what other use it is applied. But it is easy to detect this fraud by a very simple experiment. Put the quantity of a pinch of snuff of the ground coffee you suspect to be adulterated on the surface of a glass of water; the coffee itself will swim, and not mix with the water, but the chiccory will sink in the water, and be seen falling down as a red powder.

3973. The substance called *Hunt's breakfast powder,* which used to be sold in the shops, consists of rye, boiled, dried, and roasted with a little butter, and then ground like coffee; it is not unlike the most ordinary description of coffee, but it has none of the fine aroma for which good coffee is distinguished; it is at least harmless. *Roasted rice* is used in India, and is considered as the best substitute; it is found to agree better with some constitutions than Turkey coffee. The seeds of the yellow water-flag, *Gladiolus luteus,* or *Iris pseudacoras,* often found growing near water, is another good substitute, known by the name of Iris coffee, or Sylvester's coffee. In North America they use, as a substitute for coffee, the seeds of the *bean-tree,* or *coffee-tree, Gymnocladus Canadensis;* but they form a poor one, as the liquor made from them is very rank and bitter.

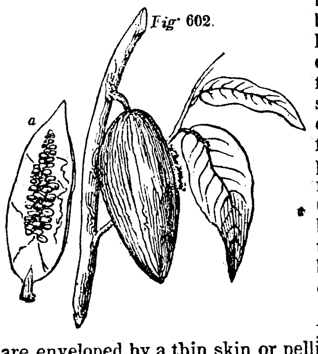
3974. *Acorns have been recommended as the best substitute* by the Academy of Sciences at Petersburgh. To communicate to them the oily properties of coffee, the following process has been used: When the acorns are roasted brown in the usual manner, add fresh butter to them in small pieces while hot in the ladle, and stir them with care, or cover the ladle, and shake it, that the whole may be well mixed.

CHAPTER XII.

Chocolate and Cocoa.

3975. *Both these preparations are made from the seeds or beans of the Cacao-tree,* which grows in the West Indies and South America. The Spanish, and the proper name, is *cacao,* not *cocoa,* as it is generally spelled; from this mistake, the tree from which the beverage is procured has been often confounded with the palm that produces the edible cocoa-nuts, which are the produce of the cocoa-tree (*Cocos nucifera*), whereas the tree from which chocolate is procured is very different (the *Theobroma Cacao*). The cocoa-tree was cultivated by the aboriginal inhabitants of South America, particularly in Mexico, where, according to Humboldt, it was reared by Montezuma. It was transplanted thence into other dependencies of the Spanish monarchy in 1520; and it was so highly esteemed by Linnæus as to receive from him the name now conferred upon it of Theobroma, a term derived from the Greek, and signifying "*food for Gods.*" The Mexican name was *chocolatl,* whence the term chocolate. The trees are raised from seed, and grow to the height of about twenty feet, resembling a young cherry-tree, and do not come into bearing until six or seven years old, but then they bear leaves, flowers, and fruit all the year round; the leaves are about four inches long, pointed, and of a dull green; the flowers saffron-coloured and beautiful. The trees grow in morassy situations, and are sheltered by larger trees. Their cultivation is very easy, requiring little attention beyond gathering the fruit when ripe. The cocoa beans are contained in pods something like a roundish cucumber deeply furrowed, about five inches long and three wide, *fig.* 602, each pod, *a,* containing from twenty to fifty beans, according to the particular variety and country where they grow, about the size of almonds, imbedded in a reddish-white pithy substance, like that of a watermelon.

Fig. 602.



The pod is smooth on the outside, green when young, but when ripe variously coloured. The beans are enveloped by a thin skin or pellicle, of a brown colour, which is taken off before they are converted into chocolate. The kernel is divided into several portions, which do not adhere together, and which easily come to pieces when the skin is removed.

In the West Indies, when the fruit is ripe, the beans are taken out of the pulp, spread out to dry, and put into bags for exportation; but in the Caraccas they are subjected to a species of slight fermentation, by which they lose a good deal of their acrimony and bitterness, and acquire more aromatic flavour. It appears that there are several species of the *cacao*, or cocoa bean, and that these differ much in their qualities. The Mexican is considered the best, but it seldom comes to Europe; that from Guatemala is much esteemed, and the beans are larger. The West Indian cocoa is among the least valuable kinds, being very oily.

Chocolate has always been a favourite beverage among the Spaniards and Creoles, and was considered here as a great luxury when first introduced, after the discovery of America; but the high duties laid upon it here confined it long almost entirely to the wealthier classes. Before it was subjected to that duty, Mr. Bryan Edwards stated that cocoa plantations were numerous in Jamaica, but that the duty caused their almost entire ruin. The removal of this duty has increased their cultivation.

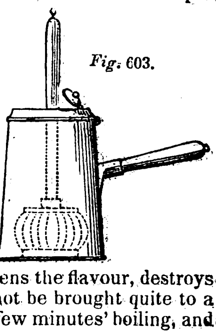
3976. *The cocoa bean has been analyzed* by Lampadius; the kernels of West Indian cocoa contain, in 100 parts, some water, 53·01 of a fat oil, 16·7 of a brown albuminous substance that contains the aroma, 10·91 of starch, 7·75 of gum, 0·9 of woody fibre, and 2·01 of a reddish matter that would serve as a dye stuff. The husks of the beans form 12 per cent. of their weight; they contain no fat, but consist of woody fibre and a brown mucilaginous extract. The fat or oil which the cocoa-nut contains, called *butter of cocoa*, may be extracted by steaming the nuts, or soaking them in boiling water, and subjecting them to strong pressure in canvass bags, or by skimming it off the water when cold. It is of the consistence of tallow, is of a mild agreeable taste, has a reddish tinge when first expressed, but it becomes white by boiling in water. From five to six ounces of the butter may be obtained from a pound of cocoa; it is not apt to become rancid like fats in general; it serves in some places to make candles, as it melts only at 122°, but it is not used here; in France it is employed for making soap. Recently a principle has been discovered in the cocoa bean very similar to caffeine.

3977. *The simplest method of preparing a beverage from the cocoa beans* is that which was employed originally by the Mexicans. They roasted them in earthen pots, and, after clearing them from the husks, which then easily separated by fanning, bruised them between two heated stones, working the oily paste into the form of cakes; and this is nearly the process employed here at present. The taste of the unroasted bean is bitterish, unctuous, rather rough and peculiar, but not ungrateful. By roasting it is considerably altered.

3978. *Chocolate*, made in the manner above described, was imitated by the Spaniards from the Mexican mode. It was extensively used in Spain, and was imported into this country as a great luxury under the name of *Spanish chocolate*. This, however, had the addition of other ingredients than the cocoa beans, to give it a more agreeable flavour; as sugar, cinnamon, vanilla, and other spices. Some have added maize, tapioca, salep, arrow-root, and substances which may be considered as adulterations. When the mixture was made into a liquid, it was poured into moulds, which gave it the form of cakes when become dry and hard. The spices added to chocolate are thought to render it less wholesome and more heating than the simple cocoa bean, and are generally omitted in our preparation of this article.

3979. *When Spanish chocolate is to be used*, a portion of one of the cakes must be scraped fine, added to a sufficient quantity of water, and simmered for a quarter of an hour; but *milling* is necessary to make it completely smooth. For this purpose, a tin vessel is made, *fig.* 603, that has a circular wheel of wood or metal within, fixed to a stem that passes through the lid, and which, being whirled about rapidly by the palms of the hand, bruises and mixes the chocolate with the water. The chocolate must be milled off the fire, then put on again to simmer some time, then milled again until it is quite smooth. From the fineness of the chocolate, there should be no sediment, and the whole should be drunk; cream is generally used with it. An ounce of the cake will make a pint quite rich. The sugar may be put in with the scraped chocolate, or added afterward. Chocolate should never be made before it is wanted, because heating it again lessens the flavour, destroys the froth, and injures the body of the chocolate. It should not be brought quite to a boil, for the oil of the nut is observed to rise to the top after a few minutes' boiling, and even on standing long on the fire.

Fig. 603.



3980. *Churchman* was a celebrated manufacturer of chocolate in this country, and he has been succeeded by *Fry*, of Bristol, who now prepares every variety of chocolate and cocoa in the greatest perfection.

3981. *Fry's Churchman's chocolate* in powder does not require milling. It is sold in small tin canisters, and is extremely convenient for travellers or persons in public offices, &c., as a cup of chocolate is made with little trouble. To prepare it, put a large tea-spoonful into a tea-cup, add a few tea-spoonfuls of boiling water, and mix it well; then fill up the cup with boiling water and stir it; add sugar, milk, or cream to suit the taste.

3982. *Chocolate paste* is another preparation by Fry, made with still greater facility than the last; it may be mixed at the breakfast-table.

3983. *Broma* is a preparation of chocolate adapted for those with whom the oily quality of chocolate does not agree. Part of the oil is extracted, and some sago, potato starch, or similar substance substituted, which renders it easier of digestion.

3984. *Milk chocolate* is made with milk instead of water. Put the milk and water on to boil, then scrape the chocolate fine, from one to two squares to a pint. When the milk and water boils, take it off the fire, throw in the chocolate, mill it well till it froths.

3985. *Chocolat à manger* is a preparation of chocolate, originally French, made up with sugar into small long cakes for eating. They are considered useful to travellers, from the great quantity of nutriment they contain in little compass. Humboldt states that, by means of this nutritive quality of cocoa, the inhabitants of some parts of South America are enabled to sustain very long journeys in crossing the deserts or uninhabited forests.

3986. *Since the cocoa beans themselves have been imported in abundance into this country,* real Spanish chocolate is nearly gone out of use, and both *chocolate* and what is termed *cocoa* are manufactured here; the difference between them being that in the former the beans, carefully selected and deprived of their skins, are perfectly levigated, so that the paste unites heartily with the water and milk boiled with it, scarcely depositing any sediment; whereas in *cocoa*, being less finely ground, there is more sediment; chocolate is so finely ground that the particles are kept suspended, and the whole is drunk, whereas in what is called simply cocoa the sediment must be allowed to subside, and only the liquid is used when poured off from the grounds.

3987. *Cocoa is prepared here for sale in several ways.* The beans are put into a heated iron cylinder similar to a coffee-roaster, having holes at the ends for suffering the vapours to escape. When the aroma is well developed, the roasting is finished; and the beans are turned out, cooled, and freed from their husks by slightly rubbing, sifting, and fanning. It is a peculiarity in the cocoa beans, that when first heated they are dry, and may then be ground to powder by a mill or by the pestle; but by continuing the process of bruising, the oil separates, and forms the whole into a soft paste One of the preparations, therefore, consists of *cocoa in powder*, which has been ground in a mill like coffee. Indeed, the best mode of having the cocoa pure is to purchase the beans or nuts, which are now commonly sold roasted, and to grind them in a large coffee-mill. Cocoa is deteriorated by keeping, and at the end of two years it has lost all its fine flavour.

3988. *To make cocoa ready for use,* an ounce is boiled in a pint and a half of water for about a quarter of an hour, and then it is to be kept near the fire to settle and become fine; after that it is to be poured off into another pot for immediate use. It is drunk with sugar and milk, or cream, like coffee. To save time, it may be boiled over night.

3989. *Cocoa paste* is prepared as follows: The cocoa beans are heated in iron cylinders, and deprived of their husks in the manner above described; the kernels are then put into an iron mortar heated by keeping lighted charcoal in it for some time, and pounded and rubbed with the pestle, also heated, till the whole is quite smooth like a paste. It is then placed upon a marble, or, what is better, a porphyry slab made hot thoroughly before the fire, and worked well with an iron roller, until it is as soft and smooth as butter; or this process is performed more expeditiously in a mill. A little sugar is added to make it dissolve readily when used. Sometimes it is put into tin moulds, and dried in square cakes. It is said, however, that much heat dissipates the flavour. To prepare a beverage from cocoa paste, nothing more is necessary than to stir it well in boiling water.

3990 *Soluble cocoa* is made in cheap little squares, and is mixed up with a little sugar, and probably sometimes with adulterating ingredients. By means of the sugar this readily dissolves, and is useful as being easily prepared.

3991. *Flake cocoa* is the cocoa simply crushed by a machine that delivers it in the form of flakes.

Since the duty has been so much reduced, cocoa has become an article of consumption among all classes.

3992. *Cocoa is extensively cultivated in the West Indies and in South America.* The consumption is immense. Humboldt estimated that in Europe, in 1806, at 23,000,000 lbs., of which from six to nine millions were supposed to be consumed in Spain. He observes that, "alike easy to employ and convey as an aliment, it contains a large quantity of nutritive and stimulating particles in a small compass. It has been said with truth that in Africa rice, gum, and shea-butter assist man in crossing the deserts In the New World, chocolate and the flour of maize have, by their portability, rendered accessible to him the table-lands of the Andes, and vast uninhabited forests." Cakes of chocolate may be considered as a kind of portable soup of the Tropics.

CHAPTER XIII.

ON SUGAR.

SECT. I.—INTRODUCTION AND HISTORY OF SUGAR.

3993. *We have stated before that sugar, or saccharine juice, is a constituent of many vegetables,* and it is accordingly extracted from several, but by far the most abundantly from a cane or reed called the *sugar-cane*, from which our sugar in common use is made. We shall first describe the manufacture and qualities of this kind, and afterward speak of some varieties of sugar which, though much less common, are yet occasionally produced from other vegetables.

3994. *History of Sugar from the Cane.*—Sugar, which has been used in Europe for several centuries as an agreeable condiment, was imperfectly known, and was not in common use among the Greeks and Romans. By our ancestors it was seldom obtained previously to the discovery of the West Indies; and at that time honey was usually employed for sweetening liquors and food. It is not a little curious that the Chinese, the most ancient nation now existing, were acquainted with the manufacture of sugar from the sugar-cane above two thousand years ago; the cane, indeed, is a native of China, and grows abundantly in that country. Chinese sugar in small quantities occasionally found its way into ancient Europe, and the Greek physicians, who procured it from the Arabian merchants, employed it as a medicine, describing it as a kind of concrete honey, which exuded like gum from canes or reeds. The Arabian navigators first brought it from India into Arabia and Greece; but it does not appear to have been transported to Rome, probably on account of its great bulk and little comparative value, which rendered it an unprofitable article of commerce. It is evident that the ancient notions of it were extremely erroneous, since solid sugar of every kind is the produce of manufacture only, and is never found adhering to the cane like gum; the juice must always be forcibly expressed, and afterward crystallized. Pliny speaks of a substance called *saccharon*, obtained from certain reeds in India: he observes that it was of a white colour, crackled like salt between the teeth, was sweet like honey, and was in lumps not exceeding the size of a hazelnut: a description which corresponds with that of the white sugar-candy made at present in Cochin-China. Our term sugar is probably derived from the Bengalee *shukkur*, the name by which it is still known in India.

3995. It was not until a considerable time afterward that the plant which produced it was brought from the eastern parts of Asia; and it does not appear to be certain at what particular period, nor by whom, this acquisition was first made. Early in the tenth century it was cultivated in the vicinity of Ormus, on the Persian Gulf, whence, no doubt, it was carried to Mesopotamia, a country celebrated for its sugar in the time of the Crusades; hence it spread into Syria, New Tyre being famous for excellent sugar in the twelfth century. By the Saracens it was introduced into Egypt, Rhodes, Cyprus, Sicily, and Spain.

3996. From a passage in an Arabian author, who wrote in 1073 (quoted by Blanquiere, Madrid, 1801), giving directions for the cultivation of the sugar-cane, and for boiling the juice, nearly in the same manner as at present, it would appear that sugar was made in Spain at least 700 years ago, the manufacture having been probably introduced by the Moors.

It is a circumstance not generally known that the sugar-cane is grown at this day in Andalusia, in the south of Spain, or, at least, was, only a few years ago, over a narrow tract between a chain of rugged mountains and the Mediterranean, about a hundred and thirty miles in length, with a medium breadth of four or five miles, the climate being sufficiently warm, with the exception of slight nocturnal frosts in some winters. The sugar is manufactured there nearly in the same manner as in the West Indies. This fact has been overlooked by almost all travellers, but has been stated in a late paper in the "Edinburgh Philosophical Journal" by Dr. Traill, who visited the country.

The Portuguese planted the sugar-cane in their newly-discovered islands of Madeira and the Canaries, whence it was afterward transferred to their colonies on the coast of Africa and in Brazil.

3997. It has been supposed that the sugar-cane was indigenous in America; this, however, is improbable, since it is not found growing wild in that part of the world. But the climate of the New World being found highly favourable to the growth of this plant, the Portuguese, who devoted themselves with much assiduity to its cultivation, and to the extraction of its sugar, for some time possessed almost the entire supply of Europe with this commodity.

From 1466 to 1580 sugar was rare in England, being procured from the Portuguese, Venetians, and Genoese, and was used only in the houses of the wealthy, or in medicine. With regard to its introduction into the West Indies, it appears that it was planted there some time before it was cultivated on a large scale for the manufacture of sugar. At first no other use was made of it than as an esculent garden vegetable, the stem being eaten, or, rather, sucked or chewed in a raw state, after being simply peeled, as is still the practice in China and in some of the East Indian islands. This will account for its having been noticed by travellers in the West Indies previously to the date of the establishment of the first sugar plantation. In 1643 the English began the manufacture in St. Christopher's and Barbadoes, and in Jamaica in 1656; the plant having flourished there in great luxuriance, it has ever since been extensively cultivated, and the produce distributed thence over the globe.

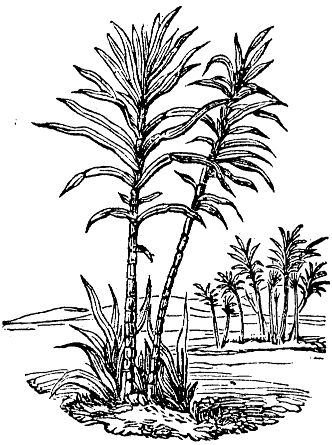
3998. *The art of refining sugar*, or making what is called *loaf-sugar*, was a discovery of some Venetians in the early part of the sixteenth century, and does not appear to have been known to the Chinese; but it was not until coffee and tea were introduced into England that sugar came into general demand here. Sugar-candy is of very early date: according to Dr. Moseley, there is an account of a shipment made at Venice for England, in 1319, of 100,000 lbs. of sugar and 10,000 lbs. of sugar-candy. Refined sugar is mentioned in a list of provisions in the reign of Henry VIII. Numerous improvements up to the present time have been made in the art of manufacturing sugar in a pure state.

SECT. II.—MANUFACTURE OF SUGAR FROM THE SUGAR-CANE, AND THE VARIOUS KINDS OF CANE SUGAR.

3999. *The sugar-cane* (*Saccharum officinale*) is a species of large, jointed reed, or grass, of which there are several varieties; but all of them appear to have been natives of the eastern parts of Asia only. In some districts of Bengal there are canes not much thicker than the finger, which give a juice that is sweet, but which does not afford a crystallizable sugar. Of the other sugar-canes, one has a pale yellow stem, agreeing with the common cane in the West Indies; another, frequent in Hindostan, has a stem of a reddish-brown colour, giving abundance of juice.

4000. *The yellow sugar-cane* of the West Indies (*fig.* 604) grows to the height of six, twelve, and even twenty feet, according to the nature of the soil, the most favourable being a deep loam: much moisture is essential to its growth. It is propagated by cuttings only, and possesses a power of tillering like wheat, though in a less degree. The canes are not planted annually; but, as they deteriorate in size every year they continue, they are renewed in ten or twelve years, or oftener. The cultivation of sugar-canes requires hoeing and weeding very frequently, a process which is extremely laborious, particularly when performed under a tropical sun. As they grow up the lower leaves are taken off, and the wind having considerable power upon them, they are then supported by props of bamboo, or sometimes tied together by their tops.

Fig. 604.



Twelve or thirteen months after they have been planted, the canes, though not quite ripe, abound in sweet juice, but mixed with much mucilage; and if they are cut at that time, which is sometimes done, though improperly, the sugar procured from them does not crystallize so well, on account of the mucilage. This is said to be one of the causes of the inferiority of East India sugar: if the canes, on the other hand, remain too long before they are cut, they throw out their flowers, and much of their sweetness is dissipated. The joints in one stalk are from forty to sixty in number, and from one to three inches apart. The young shoot ascends from the earth in an almost straight line, and is surrounded by a tuft of dark green leaves. A field of canes, when in full blossom, is extremely beautiful.

Of late years, another variety of the sugar-cane, a native of Otaheite, has, in many places in the West Indies, superseded the common sugar-cane, as it affords a somewhat larger proportion of sugar, is sooner fit to cut, and the juice is more easily clarified.

4001. *When the canes are ripe, they are cut down close to the stool;* the stems are divided into lengths of about three feet, which are made up into bundles, and carried without delay to the mill to have their juice extracted by crushing.

The crushing mill is usually a pair of fluted rollers, of wood or cast iron, and turned with levers by men who pass the canes one by one between them. The juice, as it is squeezed out, runs down into a reservoir. These mills are worked also by horses, oxen, wind, or steam. By the pressure of the rollers, the canes are not only squeezed quite dry, but sometimes reduced to fragments. The refuse, or macerated rind of the cane, which is called *cane-trash,* serves for fuel to boil the liquor in the subsequent operations. The juice which has been thus expressed is strained to separate it from pieces of the cane and other coarser impurities, and then is conveyed by a trough to the boiling-house.

4002. *In describing the manufacture of sugar* from the cane juice, we propose first to give the process which has been long followed in the West Indies, and afterward to mention those improvements which have been lately introduced.

4003. *In the boiling-house* the cane juice is received into one of the flat-bottomed copper pans, or caldrons, called *clarifiers,* of which there are generally three. The raw juice is so exceedingly fermentable, that, in the climate of the West Indies, it will scarcely remain longer than twenty minutes before this change commences; and as the least degree of fermentation materially affects both the quality and quantity of the sugar, it is necessary that the clarifier should be large enough to work off the liquor with great expedition. The clarifiers are capable of holding from 300 to 400 gallons, on plantations which make from fifteen to twenty hogsheads a week. Each clarifier is furnished with a siphon, or a cock, to draw off the liquor clear and free from the scum which is thrown up during the boiling.

When this clarifier is charged, in order to assist in the separation of the gum, oil, and other vegetable principles which are intermixed in the expressed juice, and for the purpose of neutralizing some acid contained in it, a quantity of quicklime (generally brought from Bristol) is stirred in, after having been mixed with a little cane juice to the consistence of cream. In this first part of the clarifying process, the liquor is not suffered to boil; but as it grows hot, a crust or thick scum begins to rise, and when it has reached within a few degrees of the boiling point, the damper of the fire-flue is closed, and the liquor remains undisturbed for about an hour, in order that all the impurities may have time to rise to the top. The liquor is now drawn off clear by a siphon, or cock, into the next pan, called the *evaporating copper;* in this it is made to boil, and the scum is removed by skimmers as it rises. The liquor ought now to be bright, and of the colour of Madeira wine. If it is not sufficiently bright, it is diluted with lime-water, which, by rendering the impurities insoluble, throws them up in the form of scum. From the great evaporating copper, the liquor, now considerably reduced in quantity, is transferred by ladling to a smaller copper; and when farther evaporated in this, it passes into the smallest, called the *teache;* here the boiling is continued till the liquor is sufficiently condensed for granulation. From the teache it is ladled into the coolers, which are shallow wooden vessels, about eleven inches deep, and capable of holding a hogshead of sugar. Here the liquor cools, and the sugar crystallizes, or concretes in small irregular crystals, or *grains,* which are kept from uniting together by the liquid, now in a viscid state, called *molasses,* the granulation being assisted by stirring the mass with wooden stirrers.

4004. *When all the sugar appears to have grained,* it is taken to the *curing-house,* which is an airy building, containing a large cistern below, and open joists without boarding above. Empty hogsheads without headings are ranged on these joists, and the bottom of each hogshead is pierced by holes, through each of which a plantain leaf is thrust, long enough to stand above the top of each hogshead, and to reach a few inches below the bottom. The sugar from the cooler being put into one of these casks, the molasses gradually drains from the granular part, percolating through the spongy plantain stalks, and dropping into the cistern below. In about three weeks the sugar is sufficiently cleared and dry, when it is packed into hogsheads ready for exportation. The sugar thus obtained is called *Muscovado,* and is the raw material whence the sugar-bakers in Britain make their loaf, or refined lump sugar.

4005. Part of the Muscovado sugar, on arriving in England, is purchased by the grocers, and constitutes the brown or moist sugar of the shops, and they select it according to its cleanness, its bright colour, and dryness.

The planters in our colonies have generally sent their sugar to Britain in the state of Muscovado; but in the French, Spanish, and Portuguese settlements it has been usual to convert it into what is called *clayed sugar,* which was formerly much used in Britain for domestic purposes under the name of *Lisbon sugar,* and is often mentioned in receipts.

4006. To prepare Lisbon sugar, a quantity of sugar from the coolers was put into conical pots with their points downward, and having a small hole at the bottom; the molasses which drained from the sugar dropped out through the hole into a jar intended to receive it. In about twelve hours a quantity of clay was laid upon the top, and kept moistened with water, which, oozing gently from the clay through the sugar, dilutes the molasses, and causes more of it to come away than in the hogshead, leaving it whiter than at first. This Lisbon or clayed sugar is afterward dried, and is purer than Muscovado; it is used in many places for the same purposes as loaf-sugar is with us.

4007. *Refined sugar is made from Muscovado sugar* in the following manner: The raw sugar is put into vessels charged with lime-water and the serum of bullock's blood, or white of eggs, well mixed. After standing a night to dissolve, fires are lighted under the bottom of the boiler, and as soon as the liquid begins to boil the albumen or serum of the blood coagulates and rises to the top, carrying with it all the impurities of the sugar, and these are removed by a skimmer. The other part of the blood, the clot, does no injury, as it is not soluble in the liquor, and therefore comes away entirely in the scum, none of it remaining, as some erroneously imagine, in the sugar which we use. The liquid is kept gently simmering for some time, being skimmed all the while; the heat is then increased, and the sugar made to boil rapidly until it is concentrated sufficiently; it is then transferred to the coolers, where it is violently agitated with wooden oars till it is granulated. In this granular state it is poured into conical earthen moulds, or pots, having a small hole at their pointed ends. When sufficiently cold, these moulds, containing the sugar loafs, are set, with their broad ends uppermost, over earthen pots; the hole at the small end is opened, and the treacle, or coloured sirup, runs out at the points of the moulds, in consequence of which the sugar is much whitened. After this, a paste of pipe-clay is poured upon the bottoms of the loaves to the thickness of an inch, and the water that percolates through the sugar washes down all remains of the treacle that adheres to the minute crystals, leaving the sugar white. The clay is of no other use than to prevent the water from running down too fast, which would dissolve the sugar. A sponge would answer the same purpose. This process of claying is repeated several times, when necessary, to make the sugar quite white, and the loaves are then set in a stove to dry.

4008. *Treacle, or molasses,* drained from the Muscovado, is the uncrystallizable part of the saccharine juice, either naturally so, or rendered uncrystallizable through defects in the process of boiling. It contains a large portion of sweet or saccharine principle, and is therefore, particularly on account of its cheapness, a useful article of domestic economy. It is considered as very wholesome, and children are generally fond of it. M. Cadet has shown that it may be deprived of its peculiar taste by boiling for half an hour with pulverized charcoal; the saccharine liquor is then strained from the charcoal, when its flavour is found equal to that of sugar. Treacle is found useful for making beer, rum, and the very dark sirups, as that of poppies, &c.

4009. *Several improvements have lately been made in the manufacture of sugar,* a short account of which may be interesting.

In the manner in which it has been usual to refine raw sugars, a large quantity of molasses is separated, so much sometimes as from twenty to thirty-five per cent., and it had been supposed that in the juice of the sugar-cane there were two distinct kinds of sugar, one crystallizable, and the other not capable of being crystallized, the latter being highly charged with colouring matter, constituting the molasses; and that the process of refining consisted merely in separating these two from each other. But it is now supposed that this is not the most correct view of the subject; and that the molasses is not an original and essential part of the cane juice, but is a portion of the sugar which has been charred, and thus rendered uncrystallizable in consequence of the very high degree of heat which they were obliged to use in boiling the sirup in open vessels. The formation of molasses is, consequently, so much loss of sugar. Various plans have accordingly been devised for diminishing this production of molasses, and, consequently, of increasing the quantity of sugar; and some of these have been very successful.

4010. *To avoid the action of the fire upon the bottom of the boiler,* a method was employed of boiling the sirup in coppers without fire-places, and merely by forcing heated whale oil through a coil of metallic pipes lying in the midst of the sirup within the boiler. This mode prevented, in a considerable degree, the burning of the sugar and formation of molasses. Oil was used because it is capable of receiving a very high degree of heat, but not sufficient to burn the sugar.

4011. Lately a process analogous to the mode of making Lisbon or clayed sugar, but superior in efficacy and expedition, is now coming into use in the British West India plantations, being the subject of a patent. The raw or Muscovado sugar, moistened with a little water to dilute the molasses, is put into a vessel having a perforated bottom, and placed over another which is exhausted of air by means of an air-pump. In consequence of this vacuum being formed, the pressure of the atmosphere drives the molasses down through the sugar, leaving the latter very white and pure.

4012. Heating the coppers in which the sugar is boiled by steam, at a certain degree of compression applied to the outside, instead of the direct action of fire, is another useful improvement that has been made upon the old method of boiling. This prevents the sugar from burning.

4013. *But the greatest improvement in the manufacture of sugar* was made about thirty years ago by the Hon. Mr. Howard, a gentleman eminently skilled in chemistry. From the well-known principle that boiling water, or the conversion of it into steam, takes place at a lower degree of temperature when the atmospheric pressure is taken off, Mr. Howard conceived the idea of constructing the evaporating pans in such a manner that the atmospheric air could be removed from the surface of the liquid in them by an air-pump; and thus the solution of sugar could be made to boil or evaporate in vacuo, and, consequently, with a much lower degree of heat. The advantage of this may be imagined from the fact that, whereas in the old process of boiling in the air, sixty-three pounds only of refined sugar were produced from a hundred weight of Muscovado, by this improved method they got seventy-eight pounds. The saving of sugar and improvement of quality were such as to make the patent right, which secured the emoluments of the process to the inventor and other parties, worth many thousand pounds a year; and scarcely any instance is known of so much money having been made in so short a time by any invention. The patent having expired some time, this process is now generally employed; and lately, West India planters, having applied the principle in boiling their sirups, obtain pure raw sugar direct from the cane juice, and much whiter than before.

4014. By the old process of boiling the sirup in making the raw sugar, the temperature advanced as the boiling went on, in consequence of the concentration of the liquid which prevented its ready evaporation, so that the heat, amounting to 218° or 220° and, consequently, exceeding the heat of boiling water, occasioned the charring of a good deal of the sugar. This concentration also prevented the full formation of the minute crystals of sugar; and in this manner much of the sirup that would otherwise have formed into sugar was carbonized and changed into molasses. In this state, also, the molasses was still so much united with the sugar itself, that it could not be completely separated without re-dissolving the whole, and crystallizing it afresh, which constituted the process of refining. In the new method, the temperature of the sugar in the vacuum pans does not exceed 150° or 155°, and they are heated externally by steam. When the granulation is completed in the pans, the sugar is put into the curing boxes, which have their bottoms formed of metallic gauze. The air is then drawn away from below these boxes by an air-pump, and the pressure of the superincumbent atmosphere forces down all the molasses, and leaves the crystallized sugar nearly pure. Of course, before the sirup is put into the vacuum pans for granulation, it has been clarified and skimmed as usual. Another advantage in this process is the great saving of time. Sugars cured in this manner require only a few hours' drying previous to shipment. So great is the expedition with which sugar has been made by these improvements, that at Plantation Richmond, in Demerara, the "sugar has been growing in the fields in the morning, and converted into sugar beautifully white in the evening."

The vacuum sugar, as it is called, is admitted at the same duty as ordinary raw sugar, and it bears transportation from the West Indies better than the old sugar. By the new process they get less molasses than formerly, and, of course, cannot make so much rum; but they say that the molasses is superior in quality; part of it appears to be owing to a combination of the sugar with mucilage in the cane juice, which prevents some of the juice from crystallizing.

4015. *This Demerara sugar*, made in the above manner, consists of pure, transparent, very small crystals, which are, in fact, sugar-candy of a rich taste, equal to that of refined sugar, less apt to become acescent than Muscovado, and therefore applicable to all the ordinary purposes of domestic economy. The time required for its solution being greater than that of other sugar, is in some cases a slight objection.

4016. *The East India sugar*, which has lately come into the market, is likewise made from the sugar-cane, and is whiter, though less strong than the West India Muscovado. It somewhat resembles the Lisbon, and is said to be clayed.

Sect. III.—sugar-candy, barley sugar, and sirup.

4017. *Sugar-candy consists of regular crystals of sugar.* In making refined sugar, the crystals are small, confused, and irregular; hence the whiteness and opacity of loaf-sugar; but if pure sirup, or dissolved sugar, be allowed to remain quite still and undisturbed, as the water evaporates the sugar will crystallize in certain regular forms; and if the sirup has been perfectly clarified, these crystals will be colourless and transparent, constituting white sugar-candy. Brown sugar-candy differs from this only in being formed from sirup that has not been so completely clarified. If a mass of sugar-candy, such as is usually sold in the shops, be examined, the form of the crystals can be easily made out by a little attention, and it will be observed that all the crystals are constantly of the same form, it being a law of nature that every distinct and separate substance crystallizes constantly in the same mode. There is at present much less demand for sugar-candy than formerly, when it was very generally used for coffee and tea; but it is still made in London by a few sugar bakers. The sirup from which candy is made is thinner than that employed for making loaf-sugar, in order that the crystallization may be more perfect; and the most perfect quiet is preserved, it being found that a very slight degree of agitation in the liquor will very materially diminish the size and perfection of the crystals. The sirup is poured into oblong boxes, in which a light horizontal frame, strung from end to end with fine packthread, has been previously placed for the crystals to form upon as the water evaporates when the boxes are placed in the drying stove, where they remain several days. At the end of this time, the finest crystals have formed upon the threads, and the whole inside of the boxes is found to be lined with crystals.

4018. *Sugar-candy is transparent and much harder than loaf-sugar;* its hardness causes it to dissolve less readily, except it be pounded very finely. Its inferior solubility in the mouth occasions it to be supposed by some persons not to be so sweet as loaf-sugar, but in reality there is no difference, as they are the same substance, differing only in the mode of crystallization; and the purer the sugar the sweeter it should be. It is also a very common error to suppose that moist sugar is sweeter than refined; this opinion arises from its great solubility, by which it affects our organs of taste more quickly.

4019. *Barley sugar* is sugar boiled in barley water to such a consistence that it will solidify when cold. It is flavoured with lemon peel, and then poured upon a stone slab, rolled out into little cylinders, and twisted.

4020. *Sirup* is sugar simply dissolved in water, and boiled till the water evaporates, and leaves the solution of a certain degree of strength and consistence. In making sirups, refined sugar should be employed; and if coarse sugar be used, the sirup should be clarified by heating to a froth the white of eggs with a small portion of water, and adding to it a solution of sugar and water before boiling. The albumen coagulates as the sirup boils, and, involving the impurities which the sugar contained, rises to the surface in the form of a scum, which must be carefully removed. If too much sugar be used, or if the sirup be too long boiled, the sugar soon crystallizes; and if it be in too small proportion, the sirup quickly ferments, and becomes acescent. In case of its appearing disposed to ferment, a small quantity of sulphate of potash will check the fermentation. The most certain test of the proper consistence of a sirup is its specific gravity, which, when cold, should be 1·385. But however well prepared in general, sirups are apt to ferment when kept in a temperature above 60°; and therefore the London College directs that "they should be preserved in a place the temperature of which never exceeds 55°."

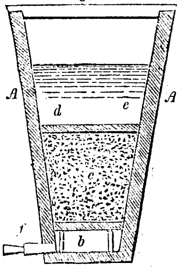
The sirup of the London Pharmacopœia is obtained by dissolving two and a half pounds of refined sugar in a pint of water by means of a water-bath, setting it aside for twenty-four hours, taking off the scum, and pouring off the clear part.

Sugar simply dissolved in water, and sugar boiled in water to a sirup, form compounds very different, as is well known to those who wish to give it to bees as a winter store. In the first case, the heat of the hive will dry up the water, and leave the sugar in crystals, which the bees cannot act upon; but by boiling, the water is made to enter into a more intimate union with the sugar, by which it is prevented from flying off, and the consistency of honey is retained, by which food bees may be preserved during the whole winter without any honey.

4021. *Vegetable sirups* are frequently mentioned; these consist of the juices of various plants boiled up with such a quantity of sugar or honey as will preserve them from spoiling by fermentation. The various kinds of these sirups are denominated from the fruits or flowers from which they are made, as sirup of oranges, of mulberries, of violets, &c. They were formerly much employed in a medicinal way, but at present they are regarded as chiefly useful in being made the vehicles of more efficacious medicines. See "Confectionery," Book XV.

4022. *A method of bleaching sirups made with raw sugar* is used in Paris, and is found so useful that many confectioners employ it instead of refined sugar. Charcoal is known to have the effect of destroying the colour of vegetable juices, and rendering them perfectly transparent. Vegetable charcoal had been used for this purpose in the sugar refineries; but it is found that animal charcoal is much more effective. The mode of using the former has been to boil the sirup with it, and then to strain the whole through a woollen cloth; but when animal charcoal is boiled with sirup it imparts to it a disagreeable flavour. The way of using it is, therefore, varied; and a filter has been contrived which answers the desired purpose. A A, *fig.* 605, is a wooden funnel lined with tinned copper. At a little distance above the bottom is a moveable bottom, *b*, supported upon feet, and pierced full of holes, with a piece of cloth laid over it; upon this is put the animal charcoal, *c*, reduced to grains like gunpowder; another moveable cover, also perforated, *d*, is put over the charcoal; and upon this the sirup to be deprived of colour, *e*, is put. The sirup passes through the charcoal and the two perforated divisions or covers without in the least deranging the charcoal, and flows into the space between the two bottoms, whence it is drawn off by a spigot, *f*. By filtering twice, a solution of raw sugar is completely bleached, and a sirup equal to that from refined sugar is produced, and the flavour peculiar to the raw sugar entirely removed. The sirups ought to be clarified and perfectly liquid before being put into the filter; and the cloths laid over the wooden divisions should be moistened before they are laid down, otherwise the sirup will find some difficulty in making its way through dry cloth.

Fig. 605.



Sect. IV.—On our supplies of sugar.

4023. *Our principal supply of sugar* is from our colonies in the West Indies, where it is raised chiefly by negro, now free labour, but it is interesting to inquire in what other parts of the world sugar is cultivated to a great extent. Besides what is made in the West Indian islands, we obtain sugar in a less quantity from Surinam, Brazil, British India, Java, and the islands of Mauritius and Bourbon.

In the numerous rich valleys of India, where the soil is productive and the climate congenial, it might be raised to any extent, sufficient to supply all Europe. But, hitherto, in Asia the process of sugar-making has been carried on in a very imperfect manner, to which alone must be attributed the inferiority of East India sugar. The sugar-cane grows to great perfection in China, but the Chinese only know the method of forming raw sugar, and sugar-candy by dissolving and crystallizing this. However, the great consumption of the higher classes throughout the East is furnished by China, which annually exports, chiefly to India, Arabia, and Persia, above three thousand tons. In Cochin-China they also make a great quantity of sugar. The annual importation of sugar at present into Britain is seen in the following table:

	Cwts.		Cwts.
From British West India Islands	3,913,269	From Java	5,950
Island of Mauritius	485,326	Philippines	35,780
British India	213,294	Foreign West Indies	223,256
Singapore, being the produce of Siam, Cochin-China, and China	38,535		4,915,619

The importation from the East is yet in its infancy: most of it is not of forty years' standing; and the manufacture of sugar in Siam, Tonquin, and the Philippines is not twenty-five years old.

4024. *Sugar may be grown, as far as climate is concerned, about thirty degrees on each side of the equator*, or the space contained between the dotted lines on the accompanying map, *fig.* 606, in which the shaded parts

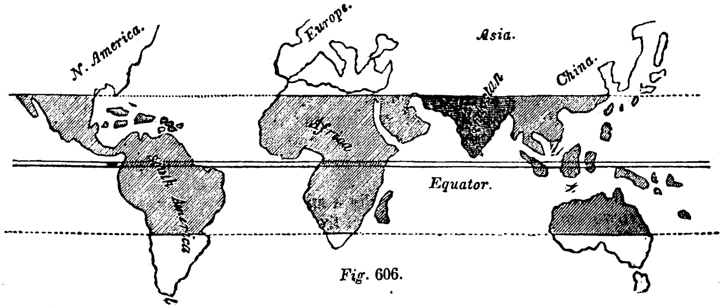


Fig. 606.

are those where it might be cultivated if the soil permits; yet, for various reasons, at present we derive comparatively only a small portion, except from a few West Indian islands, which, from their size, are barely visible on the maps; and some from Hindostan, shaded dark.

Sect. V.—Analysis of sugar.

4025. Although we have stated, Book VII., Chap. VII., Sect. V., that sugar belongs to that class of substances in which the oxyger and hydrogen exist in the proportion requisite to form water, yet the proportion of this water, or of the elements of water, varies in different kinds of sugar. Dr. Prout has paid much attention to this subject, and in a paper published in the Transactions of the Royal Society, he gives the following analysis, which has been made with extreme care:

	Carbon.	Water.		Carbon.	Water.
Pure colourless sugar-candy	42·85	57·15	East India refined sugar	42·2	57·8
			Maple sugar	42.1	57·9
Impure, or common sugar-candy	41·5 to 42·5	58·5 to 57.5	Beet-root sugar	42·1	57·9
			East India moist sugar	40·88	59·12
East India sugar-candy	41·9	58·1	Sugar of Narbonne honey	36·36	63·63
English refined sugar	41·5 to 42·5	58·5 to 57·5	Sugar from starch or potatoes	36·2	63·8

CHAPTER XIV.

SUGAR MADE FROM OTHER PLANTS BESIDES THE SUGAR-CANE.

4026. Although no vegetable produces sugar equal in quantity with the sugar-cane, yet it is well known that this useful substance may be procured by evaporating the sweet juice of many other plants; accordingly, sugar is obtained in various parts of the world from other sources, as several species of palms, the sugar maple-tree, beet root, and grapes.

Palm sugar is made only in the East; sugar from the maple-tree is manufactured in North America; and the beet root and grapes have been employed chiefly in France.

Sect. I.—Palm sugar, or jaggery.

4027. *Sugar is largely manufactured in India* by boiling the juice of several species of palm. The palms grow only in warm countries; augmenting in quantity, variety, and vigour, as they approach the equator. Although most of these afford large quantities of sweet sap, four species are only employed for the purpose of obtaining sugar. These are the wild date (*Elate sylvestris*), the Palmyra (*Borassus flabelliformis*), the Sagwire (*Borassus gomatus*), and the Cocoa (*Cocos nucifera*). All these are Oriental palms, the two latter being natives of countries within 10° of the equator. The Borassus flabelliformis is the most usual; in many parts of India it grows spontaneously, in others it is cultivated with great care. At eight or nine years of age, the trees yield a sweet juice fit for making sugar, or fermenting into liquor. To collect the juice, a man mounts to the top of the tree, having several bottles fastened to his belt. He then cuts off with his knife a thin slice from the membrane which surrounds the blossoms, and a clear sweet liquor distils from the wound; this he collects in his vessels; a good tree will afford daily about three quarts of juice, which turns sour if kept longer than three days.

4028. *To prepare the sugar called jaggery*, a little quicklime is mixed with the juice to absorb any acidity that may arise, and the latter is boiled on the day it is collected The process of making the sugar is so simple that it is produced at much less cost than that from the sugar-cane. Accordingly, it is this article, and not cane sugar, that is chiefly consumed by the poorer people.

Mr. Crawford, in the account of his embassy to Ava, mentions that, in the upper part of the River Irawaddy, there are immense groves of palm-trees grown for the manufacture of sugar, and that the price of it did not exceed a penny a pound. It nearly resembles the product which in Jamaica comes out of the cooler before it is taken to the curing-house, containing both sugar and molasses, being only a little more inspissated.

Sect. II.—maple sugar.

4029. *The sugar maple (Acer saccharinum,* Linn.) *is another of those vegetables which yield a large quantity of sugar* of the same kind as that from the sugar-cane. It grows abundantly in the southern parts of Canada and the northern parts of the United States, and proves a considerable source of wealth and domestic luxury in America. The farmers there manufacture it for their own use, and in the districts where it is produced no other sugar is employed. It is not equal in quality to West India sugar, except it be refined, which is seldom done.

The sugar or American maple is generally a smaller tree than the maple of this country; but it grows sometimes to the height of from sixty to eighty feet, and from two to five in diameter.

4030. *To procure the juice or sap,* holes in each tree are bored with an auger to the depth of about two inches, and slanting upward, and a piece of hollow cane is inserted for the sap to trickle through into a vessel placed below. The sap will continue to flow sometimes for six weeks, according to the temperature of the weather; and, according to Dr. Rush, a moderate-sized tree affords from twenty to thirty gallons of sap, from which five pounds of soft sugar may be obtained.

There are three modes of converting the sap into sugar: evaporation in the ordinary heat of the air, freezing, and boiling; the last is the most usual and the most rapid. Many farmers who make it for their own use, by no better apparatus than one or two iron kettles, obtain two or three hundred pounds in the space of a fortnight or three weeks; but manufactories of maple sugar on a great scale are now likewise established.

3031. *The usual method of making maple sugar by the farmers* is the following: it is necessary that the juice should be boiled as soon as possible after it is drawn, for if it be allowed to stand for twenty-four hours, it is apt to undergo the vinous fermentation, by which the sugar would be lost. The sap is boiled down in the woods where it is drawn, and the concentrated sap is then strained through a flannel and clarified with whites of eggs, into the iron pot for boiling it into sugar. The scum is taken off as it rises, and the whole should be well stirred. When it is supposed that most of the water is evaporated, and the sugar begins to form, a little should be taken with the ladle and tried; if the sugar is sufficiently boiled, it will granulate. The whole may now be poured into some shallow vessel, and kept well stirred till it cools and granulates. It should then be put into a wooden vessel, having holes in the bottom like a cullender, and stirred frequently for a day or two; the molasses will drain off, leaving the sugar finely granulated, and having a sparkling grain, like pounded sugar-candy, if the processes are well performed. One pound of sugar is obtained from forty pints of sap; and as, wherever there is sugar, the vinous fermentation can be induced, it is obvious that the juice could be fermented into wine, and that spirits might be distilled; indeed, a considerable quantity of rum is made from it in America, as well as excellent vinegar.

Sect. III.—beet-root sugar.

4032. Marggraf, an eminent Prussian chemist, first called the attention of the public to this subject in 1747. He was successful in obtaining from the roots of the white and red beet a sugar nearly in the state of Muscovado, or raw cane sugar.

Afterward, Chaptal, a celebrated French chemist, established a manufactory of beet-root sugar; and in 1825 there were twenty-five establishments in France. Of late, these manufactories have increased so much in that kingdom, that at present they amount to 407. The process for making it does not differ materially from that employed in making cane sugar. The white beet is the best, as giving no colouring matter; and 100 parts of the entire root afford from two to two and a half of refined sugar, exactly similar to that from the cane. In France, by various improvements, they make but little molasses, and they convert most of the Muscovado into refined sugar, which is of equal whiteness and beauty to that from the sugar-cane. Beet-root sugar is said to constitute one half of the sugar consumed in France.

Sect. IV.—grape sugar.

4033. *The grape contains a large quantity of saccharine matter mixed with mucilage;* and during the process of drying them into raisins, part of the sugar is seen to exude and concrete spontaneously on the external part of the fruit, from which it might be supposed that to obtain this sugar in a purified state would be a work of no great difficulty. *But the sugar of grapes is not of the same kind nor composition as cane sugar,* and therefore it cannot be made to imitate it. It agrees with sugar from starch or potatoes. It is not of so good a quality for domestic purposes as cane sugar, being soft, mealy, and liable to become damp; neither is it so sweet as that of the cane, that is, a greater quantity is required to produce an equal degree of sweetness, though the flavour is agreeable; it is also very liable to curdle milk, and is therefore inapplicable to many culinary purposes; and it does not answer for sweetening coffee. It is, however, made in some foreign countries, particularly in Hungary.

3034. *Although it does not appear desirable to attempt making sugar from grapes, the rob or must of grapes, or the juice boiled down to the consistence of honey or sirup,* has been long known, and is much used in some parts of France. The invention of this preparation is probably of great antiquity; and it was well known to the ancient people of Syria and Egypt, where it is still largely employed. Dr. Shaw, when in those countries, ascertained that two thousand quintals of this article are annually exported to Egypt from the neighbourhood of Hebron alone; and Dr. Russell, in his "History of Aleppo," represents it as a common article of food at that place. The boiling of the juice destroys its liability to ferment; it is boiled to a half, and sometimes to a fourth part.

SECT. V.—SUGAR FROM TURNIPS, PARSNIPS, AND GRASS.

3035. *Sugar from Turnips.*—During the continental system of exclusion, attempts were made in Germany to produce sugar from a variety of native plants, and, according to Professor Von Thaer, turnips were found best adapted for that purpose. Sugar was made from them equal, in strength, colour, and hardness, to that from the sugar-cane. *Carrots and parsnips* have also been tried, and have yielded a considerable portion of sugar. *Many grasses contain sugar.* A large grass (*Holcus Cafer*), brought from the south of Africa, has begun to be cultivated in some parts of Italy, Bavaria, and Hungary, for sugar; and what is made from it equals cane sugar. But none of these vegetables yield sugar in such quantity as to render the manufacture desirable.

SECT. VI.—STARCH SUGAR AND SUGAR FROM POTATOES.

4036. *The discovery that sugar can be made abundantly from starch* is one of the most interesting in chemistry, the principle of which has been already described when treating "On Brewing." Wheat starch is not necessary; it may be made from potato starch: 100 parts of starch are to be mixed with 200 of water, and added gradually to another 200 of water, previously mixed with one of oil of vitriol, and brought to a boiling heat in a tinned copper vessel; the mixture is kept boiling for thirty-six hours, water being occasionally added to keep up the original quantity; some bone-black is then added, and also some chalk, to get rid of the acid; it is afterward strained and evaporated, by a gentle heat, to the consistence of a sirup, and set by to crystallize. This sugar resembles that of grapes, and not cane sugar. If the quantity of oil of vitriol be in creased to five or six parts, a few hours' boiling will suffice.

It is said that eleven pounds of sugar may be obtained from 110 pounds of potatoes. From one to two parts of sulphuric acid is sufficient for each hundred parts of potatoes, if the heat be a few degrees above 212°. The heat may be applied in wooden vessels by steam.

Of late a manufactory has been established near London for making sugar from potatoes. The sugar is of the Muscovado kind, and is remarkably white, much resembling East India sugar. It is sold at a price considerably below that of cane sugar; but it is important to be known that it is entirely a different species of sugar, being much less sweet, and, therefore, in reality not a cheap sugar. There is great danger lest potato sugars should be employed to adulterate the usual sugar from the sugar-cane; indeed, we have reason to believe that this kind of adulteration is already put in practice. It is also employed for distilling potato spirit, which is said to be used in the manufacture of home-made brandy, and for adulterating wines. *Sago is employed* in the same manner as potato starch.

CHAPTER XV.

ON HONEY AND MANNA.

4037. *Honey is produced by several species of bees; but most abundantly by the garden or hive bee* (*Apis mellifica*), which is found wild in many parts of the world, and always congregated in swarms. In their wild state, they frequently inhabit the hollow trunks of trees, in which they build their combs, particularly in Livonia and Poland; but with us this species may be said to be domesticated, all of them being under the protection of man.

4038. *Bees collect, by means of their tongue, or, rather, their proboscis or trunk, the sweet juice contained in the nectaries or honey-cups of flowers.* Of this saccharine juice, a part passes into its stomach, and constitutes its food; the rest goes into what is called the honey-bag, which is an enlargement of the gullet, and when full of honey is about the size of a pea. When the honey-bag is filled, the insect returns to the hive and disgorges its contents into one of the hexagonal cells of wax which it had previous prepared for its reception, and which forms what is called the honey-comb. The cells, when filled, are sealed up with a thin covering of wax, and the honey is intended for the support of the community during the winter.

4039. *It has been questioned whether honey is not merely the sweet nectarial fluid so collected;* but it is most probable that it has been altered in some degree while in the body of the animal, because, when bees are fed upon sugar alone, they still produce honey.

4040. *The nature of the honey is very much influenced by the species of flowers* from which it is obtained, and the vegetation which supplies the bees with food. The honey afforded by bees that have access to wild thyme, lavender, rosemary, and flowers belonging to the natural order Labiatæ, abounding in aromatic and essential oils, is of the first quality; and it is said to be very bad where the bees live near to fields of buckwheat. The difference in the food occasions the honey of each country to have a peculiar character. The honey of Hybla, on the east coast of Sicily, and that of Hymettus, a mountain near Athens, were reckoned by the ancients the finest in the world; that of Crete was also celebrated; and excellent honey is still produced in some of the islands of Greece, where the bees inhabit hollow trees and rocks. Palestine is described as formerly flowing with milk and honey. The best now known is said to be from the Peak of Teneriffe. That of Minorca is also very fine; it is very white, and when new has the odour of rosemary, derived from the rosemary and other wild shrubs that grow in that island; the honey of Murcia, Valencia, and Catalonia is of the same kind. A softer, less crystalline, pale-coloured, and nearly flavourless honey is collected in Switzerland, and is known in our shops by the name of Chamouni honey. The finest honey in France is that of Narbonne; it is of a pale colour, and, on keeping, deposites larger and harder granulations than common, and is characterized by the flavour or odour of rosemary; that of Haut Provence has the fine flavour of lavender. It is, however, suspected that some of these flavours are artificial.

4041. *The whitest honey is met with in the lime-tree forests near the town of Kowno in Lithuania;* it is considered on the Continent as the most valuable, not only on account of the superiority of its flavour, but also for the estimation in which it is held for pulmonary complaints, being less heating than the ordinary kinds. The great demand for it occasions it to bear a high price, so much as two ducats per pound on the spot. This species of lime-tree is peculiar to Lithuania, and is different from the rest of the genus Tilia.

4042. *The common honey of Britain,* being chiefly derived from agricultural crops or wild plants of the leguminous kind, such as clover and beans, gorse and broom, is, when pure, of good quality, though not equal to some of those already mentioned; the Hampshire honey is reckoned the best in England. *Mr. Aikin observes* that "there is a shallow vale in Shropshire, extending from Wenlock towards Ludlow, which from time immemorial has borne the name of Apes-dale, from the number of hives formerly kept by the cottagers and small farmers who inhabit it, and who are said to have paid the priory of Wenlock a considerable part of their rents in honey. The soil is entirely calcareous, and during the whole summer it is covered with flowers. Select specimens of its honey," says Mr. Aikin, "bear a close resemblance in colour and hardness of granulation to that of Narbonne; it wants, indeed, the odour of the latter, which perhaps is not natural to it."

4043. *It is a remarkable fact that the honey of some countries is poisonous.* An instance of this kind is mentioned by Xenophon, in his history of the retreat of the 10,000 Greeks; when on the shore of the Euxine Sea, two days' march from Trebizond, those who ate of the honey found there were seized with delirium that had nearly proved fatal. Pliny speaks of another case of the same kind in the same country; the truth of which statements was confirmed in modern times by Tournefort, who ascertained that plants with poisonous flowers grew there. Dr. Barton mentions a poisonous honey in Pennsylvania, and Humboldt met with one on the Oronoco.

4044. *It has been observed, indeed, that, with respect to the wholesomeness of honey,* many persons can eat one kind with impunity, but not another.

The different species of heath which cover large tracts of hilly country in our own island, and overspread the sandy wastes of Brandenburgh, Pomerania, and, generally, of the north of Germany, afford a considerable quantity of reddish-brown honey, of a strong odour and flavour, and very liable to disagree with those who are unaccustomed to it. In the market it bears the lowest price, and little or no demand exists for it in London. It is probably the same as the heath honey (Ericæum mel) of the Romans, which, according to Pliny, is the worst of all.

4045. *Honey is a species of sugar* consisting of two varieties; one part of it is always liquid like sirup, and cannot be rendered solid or crystallized; the other may be separated, granulated, or crystallized, and made into a solid sugar. These two substances are always mixed together in honey, but in variable proportions, and the quality of the honey depends much upon the quantities of each of the two sorts of sugar. The best honey is that which contains the largest proportion of the crystallizable sugar. Both are soluble in water; but the sirupy part only is dissolvable by cold alcohol, which leaves the other untouched. To separate them, mix the honey with alcohol, and, after it has had time to dissolve, put the whole into a linen bag, and press the liquid part through; a granular mass will remain behind; to crystallize this, it must be boiled in alcohol, which will dissolve it, and then, by slow evaporation, it will crystallize into sugar. By evaporating the other solution in alcohol the sirup may be obtained in a concentrated state. Besides these two kinds of sugar, honey contains also a free acid matter not yet well understood, mucilage, and sometimes a little wax, together with colouring and odoriferous matter.

4046. *New honey appears a uniform transparent sirup,* varying considerably in colour from nearly white to a yellowish brown, intensely sweet to the taste, but having always more or less of a peculiar flavour and an aromatic odour; and besides its sweetness, it has a sharp, acidulous taste; by keeping, the colour becomes deeper, and it acquires more sharpness. It is laxative, and, when indulged in freely as food, it is liable to induce colic in some habits. After a few weeks, it generally grows thick, from the formation of small, soft crystalline grains, which remain mixed with the fluid parts. The same effect is produced by a cold temperature. The lighter-coloured honeys are the most liable to granulate.

4047. *In taking the honey from the hives*, a slice is cut off from the surface of the comb, so as to unseal the cells; after which it is laid on a sieve to allow the honey to drain out. The honey obtained in this manner is the purest and best flavoured; but sometimes a little warmth is employed, which injures the flavour. Generally, pressure is employed to save time; by this a greater quantity of honey is obtained, but as it is then mingled with some wax, and fouled by the juice of those bee-maggots which happened to be in the comb, and which are crushed by this process, the taste of the honey is deteriorated. *Virgin honey* is what is first made in a clean new hive by bees that have never swarmed. The honey made in the spring is preferred to that of the autumn.

4048. *To prevent the practice of destroying the bees* to obtain their honey, several plans have been tried: that lately put in practice by Mr. Nutt appears to be quite successful. By the method which he employs he procured 296 lbs. of honey from one stock of bees, the usual product being from 100 to 190 lbs.

4049. Honey was much in request before the discovery of sugar; at present it is little in demand, except for the purposes of medicine; the finer kinds, however, as articles of luxury, still bear a high price; that of Narbonne and Minorca are most in estimation.

4050. *Honey is sometimes blanched.* Dr. Bright, in his "Travels in Hungary," informs us that the Jews bleach common honey to such a degree of whiteness as to sell it for Kowno honey, which is very fine, and exclusively made from lime-tree blossoms. They do this by exposing it to the frost for three weeks, sheltered from the snow; the honey does not freeze, but acquires transparency and hardness. Both honey and wax may be bleached by steam, or by exposing them to a humid atmosphere; in frosty weather the operation is rapid.

4051. *Honey is clarified* by melting the best kind with water over a water-bath, adding the white of egg, and boiling it to throw up the scum; when the scum is removed, the water must be evaporated and the honey brought to its former consistence.

4052. *Honey enters into the vinous fermentation* without the addition of yeast, and yields the liquor called *mead*, of which formerly vast quantities were made before so much land had been brought into cultivation for grain. See "Mead," Book VIII., Chap. V., Sect. III.

The noted Italian liqueur *rosoglio*, which is also made at Dantzic, is prepared from a spirituous liquor and honey blanched by the Jews in the manner mentioned above.

4053. *A substance much resembling honey* may be made by boiling the must of grapes to a sirup, and the sugar of honey resembles that of grapes more than that from the sugar-cane.

Manna.

4054. *Manna has been supposed to be a species of sugar;* but its sweetness is owing to a distinct principle called *Mannite*, holding an intermediate place between cane sugar and honey. This, when prepared pure, is agreeably sweet, and free from the nauseous taste of manna; it is readily soluble in water, and instantly melts in the mouth. Manna is used only as a medicine; it is a vegetable substance that exudes spontaneously, and is obtained by incisions from the stem of a species of ash (*Fraxinus orrus*), a native of the south of Europe, particularly of Sicily, Calabria, and Greece. The juice concretes into solid masses, or is dried in the sun or in stoves. The best manna comes to us closely packed in chests, and is called *flake manna*.

Mr. Madden, in his "Travels into Syria and Arabia," mentions a species of manna, called at present by the Arabs *mann;* it is produced by a species of tamarisk that grows in Wady Amara, and near Gibel Tor (the ancient Mount Sinai). It exudes in the month of June, during the night, from the thorns of the tree on the leaves and twigs beneath, but if exposed to the heat of the day it melts. The Arabs boil it, and, after straining it, put it into leathern bags, to preserve it for use; it has much the appearance of honey.

BOOK IX.

ON MAKING BREAD.

CHAPTER I.

INTRODUCTION AND HISTORY OF BREAD.

4055. *The quality of bread is universally allowed to be a matter deserving of serious consideration;* for good bread is not merely an article of luxury, but is essential to our health. The changes which have occurred in the habits of society have, in a great measure, taken the manufacture of bread, among other things of the first necessity, out of the hands of individuals, and placed it in those of public bakers, on whose skill and probity we now depend for an article which has been emphatically termed the "*staff of* *life.*" This is, perhaps, to a certain extent, unavoidable in the present condition of things, particularly in large cities; but while many persons are thus freed from what would otherwise be a continual source of trouble, and to whom this arrangement is a convenience of no small importance, it begins to be overlooked and forgotten that there are any advantages to counterbalance the inconveniences of private or domestic baking. Previously to our determining on this question, it will be well to inquire carefully into the nature of this kind of food, and into all the circumstances connected with its production. We shall thus be enabled to form an accurate judgment how far domestic baking is worth attending to.

4056. *We shall divide the subject into several chapters:* in the first we propose giving a short history of the introduction and progress of making bread among civilized nations; in the second we shall treat of the materials from which bread is prepared; the third shall describe the practice of making bread of various kinds; in the fourth we shall point out several farinaceous substances used instead of bread in various parts of the world; in the fifth we shall describe the construction of bakers' ovens, with some remarks upon baking.

4057. *History of Bread.*—Of the various kinds of aliment to which civilized man has had recourse within the historical period, none has been so universally employed as bread. The cultivation of grain for the regular supply of a superior vegetable food always denotes an advanced state and settled condition of society, from which may be dated the accurate division of territorial property; for the districts which had been used for hunting and pasturage were not divided with any degree of exactness.

Like most arts of primary importance, the invention of bread long preceded the period of its history, which is involved in the usual obscurity of early times. The Greeks were accustomed to deify the authors of discoveries, and they accordingly ascribed the introduction of agriculture to Ceres, and the invention of bread to Pan; but the Chaldeans and Egyptians were acquainted with these arts at a still more remote period. The sacred writings make mention of it in the days of Abraham: "And Abraham hastened into the tent to Sarah, and said, Make ready quickly three measures of fine meal, knead it, and make cakes upon the hearth." In the paintings recently discovered in the tombs of Egypt, the various processes used by the ancient Egyptians in making bread are distinctly represented.

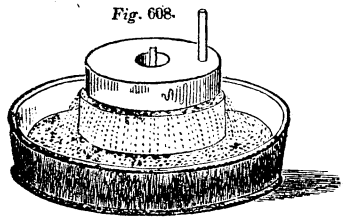
But when we consider how small is the quantity of nutriment that might have been expected from seeds like the farinaceous grains, we may suppose that these would not have been resorted to at first, except in the deficiency of larger supplies of food derived from hunting, fishing, and fruits. We find at the present day some of the savage tribes in America using occasionally, when unsuccessful in the chase, the seeds of a wild corn; but they never attempt its cultivation. Some kinds of grain are more easily deprived of the chaff than others, which have a hard or horny covering so close that it cannot be separated by mere rubbing. Also, grain, when full grown, but yet soft and milky, is more palatable than the same when dry and ripe; and the species with naked pods are often used as food in this state by persons in low or very simple conditions of society, without any farther preparation than merely toasting them. Ears of maize are thus treated by farmers in the United States of America; and Hasselquist, in his "Travels in Palestine," gives us an account which has been confirmed by late travellers. "On the road from Acre to Leide," he observes, "we saw a herdsman eating his dinner, consisting of half-ripe ears of wheat, which he roasted and ate with as good an appetite as a Turk does his pillau. In Egypt such food is much eaten by the poor, being the ears of maize or Turkish wheat, and of their *dhourra*, which is a kind of millet. When this food was invented, art was in a simple state; yet the custom is still continued in some nations, where the inhabitants have not, even at this day, learned to pamper nature."

Boiling demands the possession of metals and the art of working them, or of some material capable of resisting fire; but this is so simple and advantageous a mode of using corn of all kinds, that it was probably employed long before the more artificial method of grinding the grain into meal, and baking it as bread. Burckhardt observes that the inhabitants of Nubia boiled the green ears of barley in water, and ate them with milk.

4058. In the remotest parts of Scotland, until very lately, a custom existed among the poorest classes, which may very well illustrate the manners of the most simple nations of antiquity. Barley, well dried by the fire, was put into a hemispherical cavity worked out of a block of stone, *fig.* 607, where it was beaten for a short time by a wooden mallet until the husk was pretty well separated: a small quantity of the bruised barley was next taken up in the hand, and cleaned by blowing gently with the mouth, which was sufficient to drive away the husks; and the cleaned barley was then put into the pot for broth. Those who are not accustomed to trace the progress of inventions have no idea of the slowness with which they are improved. It seems very easy to grind corn into flour, yet probably ages elapsed before

Fig. 607.

Fig. 608.



this was properly effected. The *quern, fig.* 608, used in the Highlands of Scotland, was, perhaps, a legacy left to this island by the Romans, who were accustomed to carry hand-mills in their camps, as is seen in the Trajan columns; or it may have been used by the Celtic nations, as it was known in the East at a period preceding that of the earliest records. It is thus described by Dr. Johnson: "The quern consists of two stones, about a foot and a half in diameter; the lower is a little convex, to which the concavity of the upper must be fitted. In the middle of the upper stone is a round hole, and on one side is a long handle. The grinder sheds the corn gradually into the hole with one hand, and works the handle round with the other. The corn slides down the convexity of the lower stone, and, by the motion of the upper, is ground in its passage." This, the simplest, and no doubt the most ancient of all corn mills, will soon, perhaps, be no longer seen in this island; but it has been discovered among the inhabitants of the Himalayan regions, where many Celtic customs may be traced. The quern illustrates so well the usual millstones by which our flour is now ground, that it is not necessary to add anything except to say that our corn mills may be considered as querns upon a large scale driven by machinery; but the grinding surfaces of millstones have radiating lines cut into them for the more effectual bruising and cutting the grain, and reducing it to the state of powder. It is unnecessary to pursue the history of corn mills through those ages when attention was successfully turned to the best methods of saving labour, and when the science of mechanics had brought under contribution the natural powers of water, wind, and steam. Before the art of converting the nutritious matter of corn into so convenient and portable a substance as bread, various expedients, no doubt, were resorted to; the modern Italians at this day consume the greatest part of their flour in the state of maccaroni and vermicelli, and in the other forms of polenta or soft pudding.

The *pottage*, or *porridge*, of the northern part of Britain, made by boiling meal in water or milk, and the *brose*, consisting of roasted meal stirred up in the liquor in which salted meat has been boiled, are more humble remains of very ancient customs.

We may conceive, then, that the preparation of unfermented bread, or cakes, was as early as the use of grain; since the method of making them is so simple that it would easily suggest itself to the rudest nation.

4059. *At what time, and by whom, the art of fermenting bread was discovered is not known;* but accident is very likely to have given rise to it in more places than one. We learn from the Scriptures that leavened bread was known to the Israelites, as it was also to the Egyptians and inhabitants of Greece; but it appears that fermented bread was not introduced into Rome until 550 years after its foundation, or about 200 years before the Christian era: Pliny informs us that the Romans learned this, with many other improvements, during the war with Perseus, king of Macedon. The armies, on their return from Macedonia, brought Grecian bakers with them into Italy; and these were called *pistores*, from their ancient practice of bruising the grain in mortars. The profession of a baker was held in great estimation; and in the reign of Augustus there were 329 public bakehouses in Rome, which were chiefly occupied by Greeks, who long continued to be the only persons who understood the art of making good bread. These bakers were incorporated, and enjoyed considerable privileges, and had the care of the public granaries. The art of baking fermented bread found its way into Gaul; but it seems to have remained long unknown in the north of Europe. In the middle of the sixteenth century, unfermented cakes, kneaded by the women, were the only bread known in Sweden and Norway. In this country, probably, the baking of bread was at first universally a part of domestic economy, and it does not appear at what period it became a distinct profession; nevertheless, it is so at present, more or less, in every country of Europe; and the practice is nearly the same in all.

There is reason to think, from a passage in Pliny (*Nat. Hist.*, lib. xviii., c. 7), that the ancients were acquainted with the use of yeast in fermenting bread; yet it was only towards the end of the seventeenth century that it became generally employed for this purpose in the north of Europe. About this time, the bakers of Paris brought yeast from Flanders for the purpose of baking, and as a substitute for leaven. Although by this means the bread was manifestly improved both in appearance and flavour, the French government prohibited the bakers from employing yeast in its manufacture under a severe penalty, in consequence of the representations of the College of Physicians in 1688, who declared it to be injurious to health. This order was, however, evaded; the yeast was put into sacks in Flanders, and the moisture being suffered to drop out, it was secretly brought in a dry state to the capital of France. The superiority of yeast bread in every respect soon became apparent; the decisions of the medical faculty were forgotten; the prohibitory laws were allowed tacitly to sink into oblivion, and the new mode of baking found its way into other countries.

4060. *The history of bread is, therefore, naturally divided into three parts*, consisting of so many remarkable stages of improvement in the art: first, the formation of unfermented bread; second, the fermentation of leavened bread without yeast; third, the fermentation of bread by means of yeast, which is the method now in general use. The subject of bread-making will be treated of most distinctly by following this order, which is not only historical, but also the most simple. But before proceeding to describe each of these, we must take a view of the materials of which bread is composed.

CHAPTER II.

MATERIALS OF WHICH BREAD IS COMPOSED.

Sect. I.—GENERAL OBSERVATIONS ON THE CEREALIA.

4061. *In our general observations on food, we explained at some length the chemical principles in the various products of the vegetable kingdom*, and pointed out that they were distinguished from each other, as to their nutritive properties, by their abounding more or less in their proportions of starch, gluten, mucilage, sugar, jelly, fixed oils, and acids. The first three constituents are the most valuable, and plants which contain a large proportion of them are termed *farinaceous*, because they yield, on being dried and pounded, or ground, a farina, or meal, which, when boiled in water, forms a pulpy substance, sometimes used as food, and which, by proper management, can likewise be converted into bread.

4062. *Among the farinaceous vegetables, by far the most important are the seeds of the Cerealia, or corn plants*, which belong to the natural order of Gramina, or grasses, in botanical systems. Next to the Cerealia are the Leguminosæ, or leguminous plants, whose seeds are found in a pod botanically called a legumen, such as pease and beans. Many roots, fruits, and even the stems of foreign trees, yield a large proportion of farina, of which the most valuable that we possess is the potato. Almonds, walnuts, and filberts contain farina mixed with oil and mucilage, but they are not, with us, employed for the purpose of making bread. Other substances will be mentioned at the end of this article; but at present our object is to confine ourselves to such farinaceous materials as are in common use in this country for the manufacture of bread.

4063. *It appears to be one of the wise dispensations of Providence*, of which the study of nature furnishes so many and such striking examples, that the Cerealia, or corn plants, are distributed all over the face of the earth, or, at least, in all those parts where it is most desirable that man shall fix his abode; and they are likewise now become to such a degree the object of culture, that no civilized country is destitute of this valuable addition to its means of sustenance.

4064. *The principal corn plants* are wheat, rye, oats, rice, maize, and millet; there are many others belonging to the same tribe, but they are little in request, on account of the smallness of their seeds. The term *corn* is generally applied, in every country, to that species particularly which is raised in the greatest quantity, and which is most generally employed; thus, in America, maize, almost solely, is called corn. Wheat is the most valuable of the grains used in the fabrication of bread; it is, in fact, the only one of which light, porous bread can be made; the others are only used in climates not suitable to the cultivation of wheat, or for malt, or for the food of cattle.

4065. *All the corn plants are annuals*, the head, or ear, containing the seed being supported upon a straw, or culm, which is hollow, and divided by joints (hence they are called culmiferous plants), a single leaf proceeding from each joint. It is worthy of remark that the stems are coated with a glossy varnish, consisting of actual silex, or flint, which the vegetable has the power of extracting from the soil and dissolving, although the particular means by which this is effected are unknown to us. This is well seen in the bamboo and canes, which, though not Cerealia, belong to the Gramina. Masses of spongy glass derived from this source have been found where stacks of corn have been burned down; and this is the reason why the ashes of straw form an excellent polishing material, the siliceous part not being destroyed by the combustion.

4066. *The Cerealia are all remarkable for their extraordinary power of multiplication*, each grain or seed throwing out several stalks, all of which bear ears; and the number of these is not limited, but depends upon the more or less favourable circumstances. This increase in the stalks is called *tillering*, and is performed by a second set of roots, called coronal roots, shooting out at the surface of the ground subsequently to the first or seminal roots. Some extraordinary instances are related of this kind of multiplication. In 1660, a plant of barley was preserved in Paris, as we are told, by Kenelm Digby, that had 249 stalks springing from one grain, and in the ears were counted 18,000 seeds. A still more extraordinary fact is related in the Philos. Trans., vol. lxviii.: Mr. Miller, of Cambridge, found that a single grain of wheat, sowed on the 2d of June, had produced 18 stalks; on the 8th of August he took up the plant, and divided the stalks from each other, each having its root, and planted them again separately. Every separate plant now again tillered, throwing out fresh roots and stalks. These he again took up, divided, and planted as before, and so on several times, till by the next April they had multiplied to 500 plants, all extremely vigorous; the number of ears from these amounted to 21,109, and the number of grains to 576,840. But such instances are uncommon. The straw of the Cerealia is useful as fodder for cattle, for thatching, and various other purposes.

4067. *The corn plants have been so long the produce of cultivation*, that all knowledge of their native countries is lost; and, indeed, they have undergone so much change from the progress of agriculture, and so different are they at present from what they were in their wild state, that the originals cannot be recognised with certainty; nor is it clear when these plants are discovered in unfrequented regions, whether they may not have been brought there at some distant time, and have remained as a trace of ancient civilization. It is most probable, however, that it was from the central parts of India the rest of the world has derived this important gift of Providence, as well as most of the other useful vegetables and fruits cultivated in Europe. They were all, except maize, unknown in America on its discovery.

The corn plants do not grow equally in all climates; and the globe may be divided into several zones, according to the prevalence of some particular grain. Rice requires the warmest climate; next maize; then wheat, rye, barley, and oats. The first three are the most extensively distributed; maize has the greatest range of temperature; but rice may be considered as supporting the largest number of the human race. The natural distribution of these grains over the globe depends not only upon climate, but likewise upon the industry of man, the state of commerce, and other causes by which the limits of their cultivation are extended.

4068. *The following view of the distribution of the Cerealia* is abridged from a German work quoted in "Jameson's Journal" for 1835:

Within the polar circle agriculture is found only in a few places. In Siberia, grain reaches to the utmost only to 60°; in the eastern parts scarcely above 55°; and in Kamtschatka there is no agriculture. On the northwest coast of America the polar limit of agriculture appears to be somewhat higher; for in the more southern Russian possessions barley and rye come to maturity. On the eastern coast of America it is scarcely above 52°. It is only in Europe, in Lapland, that grain is cultivated at so high a latitude as 70°; beyond this, the bark of the pine, dried fish, and here and there potatoes, supply the place of grain. The grains which extend farthest to the north in Europe are barley and oats; these, which in the milder climates are not used for bread, afford to the inhabitants of the northern parts of Norway and Sweden, and part of Siberia, their chief vegetable food. Rye is the next which becomes associated with these. This is the prevailing grain in a great part of the northern temperate zone, namely, in the south of Sweden and Norway, Denmark, and in all the lands bordering on the Baltic, the north of Germany, and part of Siberia. In the latter, another very nutritious grain, buckwheat, is very frequently cultivated. In the zone where rye prevails, wheat is also generally to be found, barley being here chiefly cultivated for the manufacture of beer, and oats supplying food for horses.

To these there follows a zone in Europe and Western Asia, where rye lessens or disappears, and wheat almost exclusively furnishes bread. The middle or south of France, England, part of Scotland, a part of Germany, Hungary, the Crimea and Caucasus, as also the lands of Middle Asia, where agriculture is followed, belong to this zone. Here, also, the vine is found; wine supplants the use of beer, and barley is, *consequently*, less raised. Next comes a district where wheat still abounds, but no longer exclusively furnishes bread, rice and maize becoming frequent. To this zone belongs Portugal, Spain, part of France on the Mediterranean, Italy, and Greece; farther, the countries of the East, Persia, Northern India, Arabia, Egypt, Nubia, Barbary, and the Canary Islands; in these latter countries, however, the culture of maize or rice towards the south is always more considerable; and in some of them several kinds of Lorghum (Doura) and Poa Abyssinica come to be added. In both these regions of wheat, rye only occurs at considerable elevations; oats, however, more seldom, and at last entirely disappear, barley affording food for horses and mules.

In the eastern part of the temperate zone of the old Continent, in China and Japan, our northern kinds of grain are very unfrequent, and rice is found to predominate. The cause of this difference between the east and the west of the old Continent appears to be in the manners and peculiarities of the people. In North America, wheat and rye grow as in Europe, but more sparingly. Maize is more reared in the Western than in the Old World, and rice most cultivated in the southern provinces of the United States.

In the torrid zone, maize predominates in America, rice in Asia, and both these grains are in nearly equal quantity in Africa. The cause of this distribution is, without doubt, historical; for Asia is the native country of rice, and America of maize. In some situations, especially in the neighbourhood of the tropics, wheat is also met with, but always subordinate to the other kinds of grain. Besides rice and maize, there are in the torrid zone several kinds of grain, as well as other plants, which supply the inhabitants with food, either used along with them, or entirely occupying their place. Such are in the new Continent, yams, the manihot, and the batatus, the root of which and the pisang furnish universal articles of food. In the same zone in Africa, doura, pisang, manihot, and yams. In the East Indies and on the Indian islands, Panicum frumentaceum, several palms, and cycadeæ, which produce the sago, pisang, yams, batatas, and the bread fruit. In the South Sea Islands grain of every kind disappears, its place being supplied by the bread-fruit tree, the pisang, and Tacca pinnatifida. In the tropical parts of New-Holland there is no agriculture, the inhabitants living upon the sago of various palms, and some species of arum.

In the high lands of South America there is a distribution similar to that of the degrees of latitude. Maize, indeed, grows to the height of 7200 feet above the level of the sea, but only predominates between 3000 and 6000 feet of elevation. Below 3000 feet it is associated with the pisang and the above-mentioned vegetables, while from 6000 to 9260 feet the European grains abound, wheat in the lower regions, and rye and barley in the higher. Potatoes alone are cultivated from 9260 to 12,300 feet.

To the south of the tropic of Capricorn, wherever agriculture is practised, considerable resemblance with the northern temperate zone may be observed. In the southern parts of Brazil, in Buenos Ayres, Chili, at the Cape of Good Hope, and in the temperate zone of New-Holland, wheat predominates; barley, however, and rye, make their appearance in the southern parts of these countries and in Van Diemen's Land. In New-Zealand the culture of wheat is said to have been tried with success, but the inhabitants avail themselves of the Acrostichum furcatum as the main article of sustenance.

SUBSECT. 1.—*Wheat.*

4069. In every climate where wheat can be cultivated it is raised in preference to all other kinds of corn. It contains the greatest quantity of starch, and likewise by far the most gluten, a principle from which it derives the quality that fits it for bread above every other grain. The expense of its cultivation is, indeed, somewhat greater; but from its superiority as a bread corn, it is always chosen where the climate permits, or the poverty of the country has not constrained the inhabitants to be content with cheaper food.

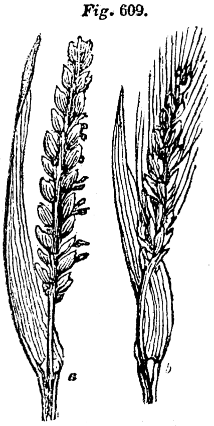
4070. *Wheaten bread is now almost universally used in England;* and in Scotland it is becoming much more general; but in the reign of Henry VIII. it was confined to the gentry, and the poorer class atè only rye, barley, or oaten bread. About the middle of the last century, very little wheat was cultivated in the northern parts of England, and the crust of the Christmas goose pies of Cumberland was composed of barley meal.

4071. *The native country of wheat is not certain;* but Bruce found it growing wild in Abyssinia. It requires a climate moderately warm; it does not extend to high latitudes, and it is finest in the warmest parts of the temperate zone.

4072. *Of wheat, agriculturists reckon several varieties;* but of these, only two are generally cultivated in this country.

1. *Winter wheat* (*a*, *fig.* 609), *Triticum hybernicum*, Linn., sown in winter, and sometimes called "Lammas wheat," is by far the most general and valuable in England, being the most productive; but it is liable to fail in cold springs. The spikes, or ears, of this wheat are long, are without awns, or, at most, have very short ones; and they are disposed in four rows, being laid over each other like the tiles in a house. Of this variety there are two sorts, the white and the red: the first is the most hardy, but the latter is said to produce the best flour.

Fig. 609.



2. *Spring wheat* (*b*, *fig.* 609), (*Triticum æstivum*, Linn.), called also "Summer wheat," is easily distinguished from the last, because it has a beard, or awns, like barley. It is sown in the end of April or the beginning of May, and ripens in autumn, generally a fortnight before the winter wheat. The grain is smaller than that of winter wheat, and it does not yield so much flour; but, though somewhat less productive, it affords greater security against unfavourable seasons, and grows rapidly. It is chiefly cultivated in Lincolnshire. Its straw is very fine, though short, and is much used for straw plait.

4073. Other varieties of wheat not usually cultivated in England are, *Polish wheat*, cultivated in Poland; *Spelt wheat*, probably the Triticum of the Romans, the Zea of the Greeks, the Epautre of the French and the south of Europe. *Victoria wheat* is a species of bearded wheat, which had been observed by Humboldt at the village of Victoria, in the province of Caraccas; this was very productive, and ripened in seventy or seventy-five days from the time of sowing, consequently affording several crops in a year. Some of the seeds have been sent over to this country by Sir R. K. Porter, and distributed to various individuals. Sanguine hopes have been entertained of its success, even in this climate, but there is not yet time to decide upon its merits. It is found to ripen about a fortnight sooner than the common wheat, which is a circumstance of importance in the northern districts; and it is thought that in the south of England it may give two crops in the year. *Nepaul wheat*, a species of wheat which has been lately introduced, brought from *Nepaul*, in India: it ripens in a very short time, and affords great produce. *Talavera wheat* was brought from Spain, and is occasionally cultivated in the light soils of Norfolk. Botanists, in general, look upon all the cultivated wheats as mere varieties produced by peculiarities in the soil and climate, and that they mostly form hybrids when mixed in the sowing. They have also been divided into the *hard* and *soft* wheats. The hard wheats are the produce of warm climates, such as Italy, Sicily, and Barbary: the wheat of Poland likewise belongs to them. The soft wheats grow in the northern parts of Europe, as in Belgium, England, Denmark, and Sweden. The hard wheats have a compact seed, nearly transparent, which, when beaten through, breaks short, and shows a very white flour within. The hard wheats contain more gluten than the soft varieties, which renders them fitter for bread and pastry. The soft wheats, those usually cultivated in Britain, have no opaque coat, or skin, which, when first reaped, give way readily to the pressure of the finger and thumb: these require to be well dried and hardened before they can be conveniently ground into flour. The soft wheats contain most starch, which fits them best for the vinous fermentation in brewing and distilling.

4074. *Wheat grown in different countries varies considerably.* The climate of the northern parts of Europe is not favourable to its cultivation. This grain has, however, been slowly making its way in this part of the world; but in Sweden, to this day, nothing is met with, usually, except rye cakes, almost as hard as flint, as they bake only twice a year. Wheaten rolls may be seen occasionally in some of the towns, but never loaves. In 1812, a baker in Gottenburgh received an order from the captain of a vessel to bake wheaten bread to the value of 1*l.*; but the baker, alarmed at the risk, required security for the payment, since, had the bread been left upon his hands, he could not have disposed of so large a quantity in that town, notwithstanding it had a population of 23,000 inhabitants.

The wheat of Essex and Kent bears a higher price than that of East Lothian and Berwickshire. The general quality of Irish wheat is about sixteen per cent., and that of Scotland eight per cent., inferior to that of England.

If we except the Russian, which is inferior, the wheat of the Continent is, in general, superior to English wheat by five per cent.: hence it is said that the London flour is inferior to that of most large towns on the Continent.

4075. *Large quantities of this grain, of a superior quality*, are imported from Dantzic and other ports in the Baltic. The best is grown in Poland and Pomerania, and is conveyed down by the rivers, in large barges and rafts, from the interior of the country. The grain is beautifully white, hard, and thin-skinned, and, in consequence of its small quantity of bran, it yields a large proportion of excellent flour. French wheat is, in general, superior to that of England. The Italians have the superiority over the French in their wheaten crops; and perhaps the best wheat of all is raised in Barbary and Egypt. The Sicilian is the finest in Europe: it is of two kinds; one is a long grain, much larger than English, and is generally boiled whole, as a substitute for barley or rice; the other is an oval soft wheat, yielding a flour that is remarkably white, and employed only in making the best sort of bread, biscuits, pastry, &c.; but, from government restrictions, very little is exported.

It is said that a very hard wheat is grown at Odessa, that contains more sugar than the French, and that the starch in it differs from that of ordinary wheat flour in being in more transparent grains, resembling gum, and absorbing less water; but a softer wheat is grown at the same place. The wheat of the south of Europe and other warm climates abounds more in gluten than that of more northerly countries, and consequently is more nutritious; it is also fitter for making maccaroni and other preparations of flour, where a glutinous quality is considered as an excellence. These wheats are of greater specific gravity, harder, and more difficult to grind, than the wheat of England.

Sir H. Davy makes the following comparison:

	Middlesex Wheat.	*Sicilian Wheat.*	*Barbary Wheat.*
Starch - -	77	75	74
Gluten - -	19	21	23

Analysis of Wheat quoted by Dr. Pereira:

	French Wheat.	*Odessa Hard Wheat.*	*Odessa Soft Wheat*
Starch - -	71·49	56·5	62·00
Gluten - -	10·96	14·55	12·00
Sugar - -	4·72	8·48	7·56
Gum - -	3·32	4·90	5·80
Bran - -	—	2·30	1·20
Water - -	10·00	12·00	10·00

4076. *Wheat is liable to several diseases*, which affect the flour made from it, and render it unfit for good bread. The principal of these are the blight, mildew, and smut, which are occasioned by microscopic fungi which sow themselves, and grow upon the stems and ears, destroying the nutritive principles, and introducing matter of a deleterious kind. The farmer is at the utmost pains to keep away these intruders. Wheat, as well as all kinds of corn, is also very liable to be injured by being stacked before it is quite dry; in which case it will heat and become musty in the ricks. In wet harvests it is sometimes impossible to get it sufficiently dried, and a great deal of corn is thus often spoiled. It is generally reckoned that the sweetest bread is made from wheat threshed out before it is stacked, which shows the importance of studying the best modes of preserving it.

SUBSECT. 2.—*Barley.*

4077. This grain is next in importance to wheat, and has one advantage over it, that it can be propagated through a greater range of climate, bearing heat, cold, and drought better, growing upon lighter soil, and coming so quickly to maturity that the short summers of northern countries, which are not sufficient to ripen wheat, are yet long enough to bring barley to maturity. In Lapland it is sown and reaped within six weeks. In Spain they have two crops in one year. Its native country is not known; but it has been cultivated from the earliest antiquity by the Egyptians. It was much in use among the Romans, and formerly, also, as a bread corn in England, as it still is in Westmoreland, Cumberland, Wales, and Scotland; but in the south of Britain it is now chiefly raised for malt.

4078. *Botanists and agriculturists enumerate many species and varieties of barley;* but those chiefly cultivated in this country are,

1. *Spring or summer barley, a, fig.* 610 (*Hordeum vulgare*), in which the grains are disposed in two rows on the ear, one on each side, and its beard, or awns, standing erect. This is the species usually cultivated in the southern and eastern districts of England and Scotland: its husk is thin, and the grains large, which renders it favourable for malting.

2. *Winter barley, b, fig.* 610 (*Hordeum hexasticon*, Linn.). In this the grains are disposed apparently in six rows, but in fact the rows are only double, three of them springing

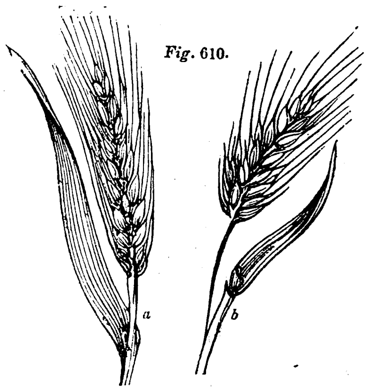


Fig. 610.

from the same point. It is cultivated chiefly in the north of England and in Scotland, being much more hardy than spring barley, and ripening earlier: hence it is better adapted for cold and high situations, such as the Highlands and north of Scotland, where a variety of it is called *bere*, and in Aberdeenshire *bigg*. Its grain is smaller and rind thicker than the spring barley, and it has less of the saccharine principle than those kinds of barley that grow under the influences of a more genial sun; it is, therefore, less proper for malt, and is going out of use for that purpose; but it makes good barley bread, and is also fit for the distiller. It appears that the thickness of the skin of barley increases according to the coldness of the climate in which it is cultivated; the cuticle of Norfolk barley being thinner than that of the species in Berwickshire or East Lothian: yet if Norfolk barley is sown in Scotland for several successive years, its cuticle is found to become thicker; but the difference between the cuticle in spring and winter barley depends upon their being different species.

3. *Common, or long-eared barley* (*Hordeum distichon*, Linn.), has the grains arranged in two rows, and is known by its very long spike or ear, and the awn being also very long. This is cultivated in many parts of England and Scotland, and is best adapted for malt of any of the varieties.

Besides these there are many other varieties, little cultivated here, as *sprat*, or *battledore* barley, *naked* barley, the awns of which fall off when ripe, *Siberian* barley, *chevalier* barley, &c.

4079. *Barley contains*, according to Einhoff, in 100 parts, volatile matter, 9·37; vegetable albumen, 1·15; saccharine matter, 5·21; mucilage, 4·62; phosphate of lime with mucilage, 0·24; gluten, 3·52; husk, with some gluten and starch, 7·29; starch, not quite free from gluten, 67·18; loss, 1·42. Sir H. Davy found Norfolk barley to contain in 100 parts, starch, 79; gluten, 6; saccharine matter, 7; husk, 8.

4080. *Dr. Thomson states* that the gluten of barley is partially soluble in cold water, as is shown in the steeping of barley for malting; but it coagulates in 120° or 130°, and falls down in gray-coloured flocks. He also extracted from the husks of barley a small quantity of an oily matter, of an asparagus green colour, and taste resembling that of the spirits from raw grain, to which, no doubt, the flavour of whiskey is owing. He likewise found in barley some nitrate of soda capable of crystallizing.

Barley has less nutritious matter than wheat, and this is differently composed. It has more mucilage, only about a third of the quantity of gluten, and as much sugar, with nearly the same proportion of starch.

It is owing to the larger proportion of mucilage contained in barley, and the smaller quantity of gluten, that this grain, though less nutritive, is a lighter and less stimulating food than wheat; and hence a decoction of barley is peculiarly adapted to invalids whose digestive powers are weak. The meal of the bigg, which grows on the mountain, is more palatable than that of the long-eared barley from a rich soil; and the barley cakes made from it in the Highlands are particularly sweet and delicate. The superior flavour of Highland whiskey is probably owing, in a great measure, to the quality of the grain.

4081. *The rapidity with which barley germinates favours its conversion into malt;* but from this circumstance, it is very liable to commence sprouting, even while yet in the ear, and quite ripe, if the season should prove very wet, yet warm and genial; and it is scarcely necessary to state that this injures its quality for bread.

4082. *Pot barley* is barley of which the husk or outer skin only has been removed by mill-stones; it is used for making broth.

4083. *Pearl barley* is the small round kernel which remains after the skin and a considerable portion of the barley have been ground off. For this purpose, the spring barley is chosen; it is steamed to soften the skin, dried, and passed between mill-stones of a peculiar kind, to take off the husk, all except what lies in the deep furrow of the seed, and which is the cause of the short dark line to be seen on pearl barley. The Scotch pearl barley is quite round, and is made from the sort called bere, or bigg. A decoction of pearl barley was the " ptisan" of ancient medicine, now better known by the name of *barley water*. Besides its use in broth, it is sometimes boiled in water, and eaten as rice with milk.

In Holland, pot barley, boiled in butter-milk and sweetened with treacle, is a common mess for children and servants.

4084. *Patent barley*, now much used for making barley water expeditiously, is the pearl barley ground to flour.

As pot and pearl barley are extremely wholesome and nutritious, it is to be regretted that they are not more used as food by the labouring classes in England, as they are in Scotland, Germany, and Holland.

SUBSECT. 3.—*Oats* (*Avena sativa*, Linn.).

4085. *This grain prefers a cold climate*, and is one of the hardiest of all the cereal plants. It cannot be cultivated in the southern parts of Europe, and is scarcely seen south of Paris. Even in England, its produce in the southern districts is inferior to that of the northern, and still more to that of Scotland. It has this advantage, that it will grow where neither wheat nor barley will flourish, and, indeed, on any land, from the stiffest clays to crude mossy soils, if sufficiently dry: it is also the most easily cultivated. Indeed, if it can be ripened before the frost sets in, the flavour of the meal is superior when the climate is rather bleak and soil not very rich.

It differs from wheat and barley in the form of the ear. It is not a spike with a single rachis, but a panicle, resembling, in some degree, the branches of a pine, from the grains hanging with their open extremities downward; these being covered by the chaff, are defended from rain, and are not liable to some diseases incident to barley and wheat.

4086. The native country of the oat is unknown. It was found by Lord Anson growing wild in the island of Juan Fernandez: a kind of wild oat is indigenous to this country, and is a very troublesome weed, from which it may originally have been produced by cultivation; but the best varieties now in use have been introduced from abroad.

4087. *The most common sort which has been long cultivated here is the white oat* (*fig.* 611); but the best variety now raised in Scotland and the north of England is the *potato oat*, which was accidentally discovered some years ago, in Cumberland, growing upon a heap of manure, in company with some potatoes: other varieties are the common *feed oat*, the *Poland*, the *Dutch*, and the *Tartarian*, &c.; all probably derived from one parent stock.

Fig. 611.

4088. *An analysis of oats* by Sir H. Davy gave, in 1000 parts, starch, 641; gluten, 87; saccharine matter, 15. From this it appears that there is less nutritive matter in oats than any other cereal grain; and the very small portion of saccharine matter which it contains renders it unprofitable for malt: it may, notwithstanding, be fermented, but with some difficulty. It contains, however, more gluten than barley, though less than wheat; and experience shows that it is very nutritive, since the labouring classes in Scotland, Lancashire, Derbyshire, and in some other parts of England and Wales, subsist and keep up their strength perfectly upon bread and other preparations made from it. Many, indeed, who are used to oaten bread, prefer it to every other kind. In the south of England oats are not employed for bread, but only in feeding horses, with whom it is supposed to agree better than any other species of grain.

4089. *Oatmeal is cooked for human food in several ways.* In Scotland it forms the dish called *pottage* or *porridge*, the universal breakfast, in many parts, of labouring people and children: deprived of the husks, it constitutes *grits*, or *groats*, much used for making oatmeal gruel, which is taken both as food and medicinally. The advantage of grits over oatmeal is, that the *fecula*, or starch, of which the meal, or farina, of the oats chiefly consists, is alone extracted by the boiling water, and that thus none of the cuticle which covers it is mixed with the gruel; but in the oatmeal, this thin cuticle, which encloses it (not the husk of the oat), is ground up with the meal, and gives to it a harsh and rough taste: for, although the gruel made of oatmeal may be strained, still a quantity of the minute fragments of the cuticle escape through the strainer; whereas, in the case of grits, this cuticle is entirely kept back, which accounts for the smoothness, as it is termed, of grit gruel. Scotch oatmeal is superior to English, which is partly owing to the superiority of the grain and the climate, but in part to the greater care employed in its cultivation. In Scotland, also, the oats are dried in a kiln previous to grinding, which gives it an agreeable flavour.

SUBSECT. 4.—*Rye.*

4090. At present rye (*Secale cereale*, Linn.) is very little employed among us for bread, and is cultivated chiefly to be eaten by the cattle as green fodder; nevertheless, rye bread was very general in England about two centuries ago, and is still used as the food of the peasantry in Russia, northern Germany, some parts of France, and great part of the north of Europe.

4091. *Rye*, according to Einhoff, *is composed of* albumen, 3·27; moist gluten, 9·48; mucilage, 11·09; starch, 61·09; saccharine matter, 3·27; husk, 6·38; moisture, 5·42. From this analysis, it appears that rye contains more gluten than any other grain except wheat, and therefore should be next to it as a bread corn.

The husk possesses an aromatic and slightly acidulous flavour, which renders it agreeable to the palate. The bran should not, therefore, be entirely separated from the flour; for if the grain be ground fine and divested entirely of the husk, the bread will be deprived of much of its pleasant taste. Rye bread is, consequently, made of coarse flour, which, together with its dark colour, has probably given rise to much of the dislike to it in this country. The quantity of gluten which it contains accounts for the facility with which it may be fermented into spongy bread, which is not the case with oats and some other grains. But bread made of it very soon becomes sour; indeed, it undergoes an acetous fermentation in the process of baking, and is thought, in consequence, to have a gentle action on the bowels.

Some persons express regret that there is here a prejudice against rye bread, since the grain thrives upon poor sandy soils on which wheat would scarcely return the seed: this is the case where rye is extensively cultivated, in the poor sandy land on the south coast of the Baltic, where its weight of corn is nearly as great as that grown upon good land, and it is produced at little expense. It also yields a large quantity of straw, good for thatching.

In some farmers' families, household bread is made of a mixture of one third rye and two thirds wheaten flour, which makes a sweeter bread than that made solely of wheat, and is preferred to any other by those who are in the habit of using it. The bread is very firm and solid, and retains its juiciness and moisture long, being also very nutritious. For this purpose, rye is sown along with wheat, under the appellation of "meslin."

4092. *From the quantity of saccharine matter which rye contains*, though less than barley, it is convertible into malt, and, of course, into beer and spirits; but it is much inferior to barley, in some respects, for these purposes, though it is said to give a great quantity of spirit. Unmalted rye meal mixed with barley, in the proportion of two parts of the former to one of the latter, is employed in Holland for the distillation of Geneva. It is said that the essential oil which rises with the spirit has a peculiar flavour, and it is thought that this resides in the husk; for the black bread of the Russians, which contains the husk ground up with the meal, has a different flavour from the fine rye bread made of rye flour only.

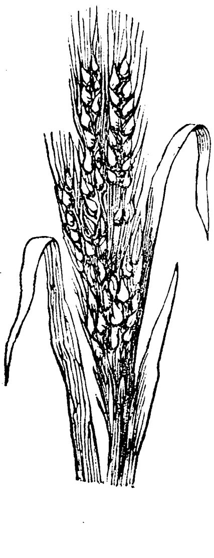
4093. *But this grain, which has been, and still is, so much cultivated as a bread corn, is subject to a disease called ergot*, or horned rye, which consists of a fungous substance that grows in it occasionally, enlarging and deforming the grain; and the effects produced upon the human constitution by this poison are so very dreadful, if what is recorded can be depended upon (and there is no reason to doubt the authenticity of the accounts which have been published), that we can scarcely regret its almost entire banishment from this country as a material for food. It is stated that those who have eaten bread made from rye infected with ergot have been attacked by disorders of the most appalling kind, such as epilepsy, which ended fatally; others have been rendered irrecoverably insane; while in others, again, the disease has been so virulent as to terminate in mortification of the limbs. It appears that these misfortunes have occurred frequently in some parts of Germany and France, particularly in Sologne, a district between the Loire and Cher. The ergot is seldom found in England, although it does occasionally appear, and not only in rye, but sometimes in wheat and other grain.

Even damaged corn is known to have acted as a fatal poison. (See this subject treated of at length in Prof. Burnett's "Outlines of Botany," p. 211, 212.) The mouldiness on stale bread is a minute plant, and always connected with a state of decomposition of the bread, which renders it very unwholesome, and even dangerous, if eaten.

Subsect. 5.—*Rice.*

4094. *Rice* (*Oriza sativa*, Linn.) *is a plant of Asiatic origin*, and has formed the chief food, from time immemorial, of the population of India and the Chinese empire. It is cultivated in Europe, but chiefly in the southern part, requiring a warm climate. It grows extensively in the rich meadows of Lombardy, and also in the province of Valencia in Spain; but the chief countries from which we obtain this grain are Carolina, into which it was introduced in the last century, and the East Indies. It probably nourishes more human beings than all the other seeds together.

Fig. 612.



4095. *Common rice is a marsh plant*, and the land where it grows requires to be flooded by irrigation, which renders the vicinity of rice grounds unhealthy, giving rise to marsh fevers. It grows very rapidly, and its cultivation is easy. There is, however, a variety of rice in Nepaul, in India, called *Hill rice*, cultivated upon the slopes of hills, where it can receive moisture only occasionally; and it has been supposed that this might in time be acclimated in England; but we should not thus obtain it at a cheaper rate than that at which it is now imported. Rice, in its growth, resembles barley more than any other corn plant, rising to the height of a foot and a half, with a stalk not unlike that of barley, but fuller of joints, and with leaves resembling those of the leek. It branches out into several stems, at the top of which the grains form in clusters. The grains or seeds grow on separate pedicles, which spring from the main stalk (*fig.* 612); each grain is terminated by an awn or beard, and is enclosed in a yellow husk. The whole head forms what is termed by botanists a spiked panicle, that is, something between a spike like wheat, and a panicle like oats. There are various methods of cultivating and dressing rice practiced in different countries: the following is the mode which Captain Basil Hall observed in Carolina:

The grain is sown in rows in the bottom of trenches made by slow labour. These ridges lie about seventeen inches apart, from centre to centre. The rice is put in by hand about the 17th of March, generally by women, and is never scattered, but cast so as to fall in a line. By means of flood-gates, the water is then permitted to flow over the fields, and to remain on the ground fifteen days, at the depth of several inches. The object of this drenching is to *sprout* the seeds, as it is technically called. The water is next drawn off, and the ground allowed to dry, until the rice has risen three or four inches. This requires about a month. The fields are then again overflowed, and they remain submerged for upward of a fortnight, to destroy the grass and weeds. These processes finish about the 17th of May, after which the ground is allowed to remain dry till the 15th of July, during which interval it is repeatedly hoed to remove such seeds as have not been effectually drowned, and also to loosen the soil. The water is then for the last time introduced, in order that the rice may be brought to maturity; and it actually ripens while standing in the water. The harvest commences about the end of August, and extends into October. It is all cut by the male slaves, who use a sickle, while the women make it up in bundles.

4096. From the pedicles the rice must be separated by a hand-flail, as no machinery has yet been devised for effecting this purpose. The next process is to detach the outer husk, which clings to the grain with great pertinacity. This is done by passing the rice between a pair of millstones removed to a considerable distance from each other. The inner coat or film, which envelopes the grain, is removed by trituration in mortars under pestles weighing from 250 to 300 lbs. These pestles consist of upright bars shod with irons, which, being raised up by the machinery to the height of several feet, are allowed to fall down upon the rice, the particles of which are thus rubbed against one another till the film is removed. It is now thoroughly winnowed, and being packed in casks holding about 600 lbs. each, is ready for distribution over all parts of the world. Each plantation has a mill. Though rice is now so largely cultivated in Carolina that it constitutes the chief produce, the swampy land being well suited to it, it is not used so much for food in America as maize and wheat, and it is mostly raised for exportation, the Carolina rice being found superior to every other. The cultivation of it is the most unhealthy work in which the slaves of Carolina are employed. They are obliged frequently to stand ankle-deep in the mud, with their bare heads exposed to the fierce rays of the sun. The consequence is, that numbers sink under it and die. This causes a constant diminution of the slaves, which the proprietors are obliged to supply by importations from the other states of North America. At the unhealthy season, when the harvest commences, all the white proprietors leave the spot, and go to higher ground, or to the north.

4097. *Rice in the native rough state*, with the husk on, is called *paddy*, both in India and America; and it will keep better, and for a much longer time, in this state than after the husk has been removed; besides which, prepared rice is apt to become dirty from rubbing about in the carriage on board ship, and in the warehouses. These facts recently suggested to some enterprising capitalists to bring it to England in the shape of paddy, and then to detach the husk. The experiment has been completely successful, and such rice may now be had in London, of Messrs. Lucas and Ewbank, as fresh in taste and appearance as any in Carolina. Paddy pays less duty than shelled rice.

4098. *Rice consists* almost entirely of starch or farina, with little or no gluten, and no ready-formed sugar; hence its nutritive qualities are very much inferior to wheat, though it is light and wholesome. Dr. Paris observes that rice is not much disposed to acescency or fermentation, and furnishes a wholesome aliment when mixed with other food; but if taken in large quantities by itself, from its low degree of stimulant properties it is apt to remain for a length of time in the stomach; and this effect is greatly increased by protracted boiling. When the stomach is in a state of relaxation or debility, it ought not to be taken without condiment; it is for this reason found necessary, in the warmer climates, to conjoin with it a considerable quantity of warm spices.

Rice, however, with proper management in cooking it, forms a very valuable and cheap addition to our farinaceous food; and in years of scarcity has been found eminently useful in lessening the consumption of flour. When boiled, it should be so managed that the grains, though soft, should be as little broken and as dry as possible; the water in which it is dressed should only simmer, and not boil hard. Very little water should be used, as the grains absorb a great deal, and consequently swell much; and if they take up too much at first, it is difficult to get rid of it. Baking it in puddings is the best mode of preparing it.

4099. *There are many varieties of rice* produced, probably, by the difference of climate and culture. The rice exported from Bengal is chiefly of the species denominated *cargo rice*; it is of a coarse reddish-brown cast, but peculiarly sweet and large grained; it does not readily separate from the husk, but it is preferred by the natives to all the others. *Patna rice* is more esteemed in Europe, and is of very superior quality; it is small grained, rather long and wiry, and is remarkably white. *Hill rice* is not imported. *The Carolina rice* is considered as the best, and is likewise the dearest in London, as it pays a much higher duty than the East Indian Rice.

Subsect. 6.—*Maize, or Indian Corn* (*Zea Mays*, Linn.).

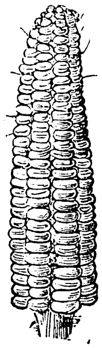
4100. *This, the noblest of the cereal grasses*, was found native in America when that country was discovered; and it now constitutes the bread corn of North America, Mexico, and a great part of Africa. It is not indigenous in any part of Europe, but is generally cultivated in the southern and eastern part of the Continent as bread corn, having acquired the name of *Blé de Turquie*, or *Turkey corn*, from its being presumed to have been introduced from the Levant by the Mohammedans after their conquest of

Constantinople. It is nearly as extensively used for the support of man as rice, but there are great differences of opinion as to its merits.

4101. *It is said to contain* very little gluten and sugar ready formed, and hence it is asserted that its nutritive power must be small; and it certainly cannot be fermented into good bread without an addition of wheat flour: and yet the people who live upon it are as strong and healthy as any, and horses and other domestic animals feed well upon it. The American and West Indian labourers think no bread so strengthening as that which is made of Indian corn; and the athletic peasantry of the Tyrol sufficiently demonstrate its wholesomeness.

4102. The American are the largest varieties; one is generally four or five feet high, but sometimes acquires the height of seven or ten feet in favourable situations, and has been seen even fourteen feet high. Its spike or ear, called the *cob* (*fig.* 613), containing the seeds, is eight or ten inches in length, and five or six in circumference. A second smaller variety is cultivated in Spain, Portugal, and Lombardy, and partially in France, forming a principal food on all the shores of the Mediterranean. These two varieties will not come to maturity in England; but a third sort, still smaller, will ripen here in ordinary seasons, and, it is supposed, might be cultivated, its growth being so rapid that it escapes the frost of spring and autumn. This last is partially used in America and Germany for making malt and feeding animals.

Fig. 613.



4103. Cobbett spoke highly in its praise, but he was probably too enthusiastic; and, upon the whole, our summers are scarcely warm enough for its successful cultivation. In America, the tender young ears, in their milky state, are roasted, and eaten with butter and salt as a delicacy, or boiled with meat. When green, they are pickled as cucumbers; dried, they keep all the year. When the grains are ripe, the skin is taken off, and the farinaceous part is boiled whole, or ground into meal, and made into puddings or cakes.

4104. *The meal*, or *flour*, is inferior to that of wheat, but mixed with it makes good bread; it is seldom used alone. In Brabant it forms the ordinary food of the peasants, fried with fat bacon. The tops, when dried, serve as fodder for horses, cattle, and sheep; and the stalks afford a sweet juice, from which the Indians of America make a variety of fermented liquors. The cob, after the seeds are taken off, is used as fuel, makes excellent corks, and forms, when bruised, a useful kind of chaff for stuffing mattresses or other purposes. Maize is far more productive than any other grain.

SUBSECT. 7.—*Millet.*

4105. *Millet* (*Panicum Sorghum*, Linn.) *is the smallest seeded of the corn plants*, being a true grass, but the number of the seeds in each ear makes up for their size. It grows in sandy soils that will not do for the cultivation of many other kinds of grain, and forms the chief sustenance in the arid districts of Arabia, Syria, Nubia, and parts of India. There are several kinds of millet.

1. *Great Indian millet*, or *Italian millet* (*Sitaria Italica*). This is cultivated in Egypt and Nubia, where it is called *dhourra*, and is used as human food, as well as for the fermentation of beer. It will grow on poor soils, and is extremely productive. It has been introduced into Italy, where they make a coarse bread from it, and it is also employed in pastry and puddings; they also use it for feeding horses and domestic fowls. It is the largest variety, growing to the height of six feet; but it requires a warm climate, and will not ripen in this country. A yellow variety, called golden-coloured millet (*Sorghum saccharatum*), is sold in the grocers' shops for making puddings, and is very delicate and wholesome.

2. *German millet* (*Sitaria Germanica*, Linn.) is cultivated for bread in some of the northern countries of Europe.

3. *Common millet* (*Panicum miliaceum*, Linn.) is the variety usually cultivated in England. There are two kinds, the brown and the yellow. The first is sometimes used as a substitute for sago.

4. *Polish millet* (*Panicum sanguinalis*, Linn.) grows abundantly in Poland, and is a native of England, but is not common. When it is cultivated, it is employed as a substitute for rice and sago, or for puddings.

SUBSECT. 8.—*Buckwheat* (*Polygonum Fagopyrum*, Linn.).

4106. This plant does not properly belong to the class of the cerealia, notwithstanding its name, which, though English, is taken from the German *beechwaizen*, beech-wheat, from the resemblance which the seeds bear to beech-mast. Its leaves nearly resemble those of the ivy; its flowers are purplish, and the seeds are triangular and of a brownish-black colour. It is not cultivated in England as human food, but it is raised partially in Norfolk, and cut, when green, as fodder for cattle. Nevertheless, it is employed as a valuable bread corn on the Continent, and in some other parts of the world. It contains some gluten and starch, though much less than wheat, and, consequently, it is not so nutritive; but it has more sugar than even barley, and the cakes made from it are sweet and agreeable.

4107. *It is much used as food in Saxony, Ukraine, Silesia,* and some parts of France, not only by the peasantry, but by the wealthier classes. The mode of dressing it is generally by boiling as pottage or puddings, or in tarts. In Tuscany it is mixed with barley, and made into bread, which is very nutritive. It is also used in North America. From the large quantity of sugar which it contains, it is employed in brewing; and a spirit is distilled from it a good deal resembling French brandy in flavour; it is said to be employed in the goldenwasser of Dantzic, and even by the gin distillers in England, who import it from Holland. Some are of opinion that its cultivation is too much neglected in England, as it grows upon very poor sandy soils, even enriching them, and preparing them to receive other grains. Its growth is rapid, though it is a tender plant, and is easily destroyed by cold, being originally a native of the south of Europe. It is excellent for fattening pigs and poultry, and pheasants are particularly fond of it. Cows feed greedily upon it, and it communicates to their milk a great richness and an excellent flavour.

Subsect. 9.—*Pease and Beans.*

4108. Formerly these varieties of pulse were much used by the peasantry of England for bread; but since the almost universal adoption of wheaten bread, they are very little employed for this purpose. Independently of their use as garden vegetables (for which see Book VII., Chap. VIII.), beans are only given to cattle as a strengthening food Pease are sometimes ground with meal, which is never made into bread alone, but mixed with the flour of wheat; and if millers be not much belied, it is said that, when pea-meal is ground fine and properly bolted, it is sometimes used for adulterating wheat flour.

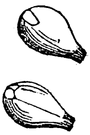
Sect. II.—PREPARATION OF FLOUR FROM GRAIN.

Subsect. 1.—*Description of Grain.*

4109. Having described the various cereal plants which are cultivated as food, we shall now call the reader's attention more particularly to those seeds from which the material of bread is usually obtained.

4110. *The seeds of the corn plants,* commonly termed *grain,* are covered by a skin, or husk, called by botanists the *testa.* The whole of what is enclosed is the *farina,* or meal, from which we derive the adjective *farinaceous,* applied to all vegetables that possess a similar substance. The farina of the grain is that part alone of which bread is generally made; the husks or bran being seldom employed except for feeding cattle, poultry, &c.; sometimes, indeed, a portion of it is ground up with the meal, but we shall now consider the meal and the husks separately.

Fig. 614.



4111. *When we examine a grain of wheat,* we find that it is enclosed in a husk which is covered by minute chaffy scales; and on one side of the grain may be observed a groove, which, when the plant is growing, is turned towards the central axis of the ear, called by botanists the rachis. The husk itself is a membranous substance investing the seed closely, but which may be readily pulled off after the grain has been soaked in warm water; and this, when ground off by the mill, constitutes the bran. Immediately beneath this exterior covering is the part of the farinaceous matter which affords the coarsest flour, called *pollard;* it is soft to the touch, of rather a darkish colour, not very easily reduced to an impalpable powder, and of a sweetish taste. It constitutes about one half of the farina, and enters into the composition of brown bread. Underneath this lies what is termed by the millers the *kernel,* or heart of the wheat, which is a hard, whitish, and almost pellucid substance. This part is readily reduced to an impalpable powder, and it alone constitutes the *fine white flour.* The internal part of wheat varies in its hardness in different countries; when the Spanish wheat was introduced into the English market, a difficulty was experienced in grinding it, from the extreme hardness of the grains. This distinction of qualities is not observed in the other grains, as in them the whole of the farinaceous matter is of a uniform quality. The flour or ground farina of wheat is therefore subjected to processes not necessary for the rest, in which it is sufficient to separate the husk bruised by grinding from the meal. The husk of barley, when dry, is very firmly attached to the kernel, and does not separate easily in grinding, and a good deal of it generally remains in the meal, which is one of the causes of the huskiness of barley bread; when the meal is ground very fine, this is less apparent. The husk of oats and of rice separate easily and entirely; oatmeal and rice are therefore quite free from the husk.

Subsect. 2.—*Cleaning Corn previous to grinding.*

4112. *Corn frequently contains impurities* which, if ground up with the flour, injure its qualities. These consist of more or less, in some cases, of the smut-ball, mildew, and substances produced by other diseases to which corn is liable; or it may be composed of sand, earth, grains partially destroyed by insects, &c.

It is cleaned from sand or any other foreign matter by putting it into a revolving hollow cylinder made of wire cloth. From that it passes into the screen for the purpose of cutting off the fine fleecy down which is found at the *rough* end of the grain, as it is named by the millers. The screen is a cylinder of sheet iron punched full of holes from the outside, the burr pointing inward like a grater. Within this is another cylinder having the holes punched outward from the inside; consequently, the two burrs point towards each other. The space between the two is about five eighths of an inch wide, and in this space is the corn. By the action of the burrs during the rotation of the cylinder, the round end of the grain is rasped off, and it falls out through the holes. The next cleansing process is by the *joggling screen and fans;* this screen has a wire bottom, and is put into a joggling motion by the mill; the corn is completely sifted by this, and the fans blow off any dirt that may adhere.

Various machines have been contrived for cleaning corn completely, but the most effectual seems to be one for which a patent has been lately obtained by Mr. Herbert, who calls it a "scouring, washing, and separating machine." The grain to be cleaned is mixed with some sharp sand, very well washed and sifted, so as to consist only of particles from a sixteenth to a thirtieth of an inch in diameter, in the proportion of five shovels full of grain to one of sand, the latter in a wet state. The whole is then put into the scouring cylinder, which is turned round for a few minutes, that the angles of the sand may rub off the impurities from the grain; after this the grain is transferred to a large sieve working under water, by which the sand is completely separated again from the grain that has been cleared. The sand falls through the sieve, and the bad grain floats to the top.

SUBSECT. 3.—*Grinding and dressing the Flour.*

4113. *Mills for grinding corn into meal or flour* are of a variety of constructions. We have, in our "history of bread," described the ancient Roman hand-mill, still used in many parts of the world.

4114. *The ordinary corn mills* in the present day are driven either by water, wind, or steam. The first two powers appear to have been known to the ancients; the latter is a modern invention. Whatever be the nature of the moving power, the grinding apparatus is the same. It consists of two circular stones, placed very near each other (*fig.* 615), the lower one, *a*, fixed, and the upper one, *b*, revolving; the grain being crushed and ground between them. The upper or grinding surface of the nether millstone is a little convex, as is shown in the annexed woodcut; and the lower or grinding surface of the upper stone is a little more concave, so that the two stones are a little farther from each other in the middle than at the edges. The corn to be ground is put into a hopper, *c*, above the millstones, and it falls down through a hole in the upper one into the space between the two. By this means the corn is, at its first entrance between the millstones, only bruised; but, as it goes farther towards the circumference or edge, it is cut smaller and smaller, and at last finally ground; when it flies out from the stones, by virtue of what is termed the *centrifugal force*, and is received into a circular tray or other vessel. In order to grind the corn both millstones have their grinding surfaces cut into grooves or channels. When these furrows become blunt by wearing, the stones are new dressed with a chisel. The millstones require to be of very hard stone, not to wear away soon: when they are of too soft a material, there is not only the inconvenience attending wearing, but the sand formed from the stone mixes with the flour.

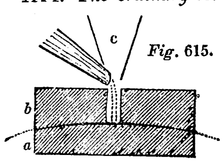


Fig. 615.

Previously to the wheat being ground in the mill, it is dried to a certain degree in a kiln by spreading it on a perforated tile floor.

4115. *Before we treat of domestic grinding*, it is proper that we should describe the various sorts of flour as they are usually prepared, as well as the principle upon which the distinction of the various qualities of coarseness and fineness of bread in common use is founded.

4116. *It was formerly the custom for the baker* to purchase the wheat and give it to the miller to grind. The miller separated it into three parts; flour, pollard, and bran. The *bran* was the outside of the grain; it was not used for human food, but only given to horses. The *pollard* was the portion of the grain next the husk, as described above; and the flour, at an average, amounted to three fourths of the grain. But by insensible degrees the manufacture of bread became separated into two distinct employments; that of the mealman, who bought the wheat and ground the flour, and that of the baker, who converted it into bread. This led to greater variety of sorts in the manufacture of flour, in order to suit the tastes of different customers; at present the following is the practice of the miller:

4117. *After the corn is ground, the separation usually made for the bakers* is as follows: When, as formerly, it was intended merely to separate the husk from the meal of wheat, as is the case in barley and oats, a sieve only was used, and only one quality of meal wa.

prepared. But as we have stated that in wheat there are two kinds of farina, the coarse immediately under the skin of the grain, and the interior white part in the centre, means have been devised for separating these also from each other. Instead of a common sieve, a cylinder of wire-work is employed for sifting or dressing, as it is called, and this is placed sloping so as to incline about 40° to the horizon. This cylinder has likewise the wires in the upper half closer together than in the lower half, so that only the finer parts of the flour can go through the first, and not through the second. The cylinder does not turn round, but, instead of that, hair brushes are made to revolve inside, and, by rubbing against the wires, force the flour through. When the whole meal or produce of the grinding is put into this wire cylinder or dressing machine, the very finest part of the flour goes through the closest wire-work, which has sixty-four wires to an inch, into a binn below, and constitutes the finest or *best flour* used for pastry, and is known by the name of *Hertfordshire whites.* What is too coarse for that is called *middlings,* and falls through the next or more open wire-work into another binn, leaving the bran and pollard to fall out at the bottom. The middlings are sometimes used for household bread, but it is occasionally reground in the mill, the stones being set closer than at first; this, in like manner, is then passed through another dressing machine, called the bolting cloth, which separates a portion of flour called *seconds.* What remains, consisting of bran and pollard, is put into the clearing off machine, which is a coarse wire cylinder, and by it the brand is separated from the pollard, the latter being used for sea biscuits and gingerbread, and for fattening hogs and poultry. A quarter of wheat, or thirty-two pecks, yields, in the London mills, 38½ flour, 8 pollard, and 12 of bran; the bulk being doubled by the grinding into flour. It is obvious from this enumeration, that so many varieties of flour, formed by the dressing, afford the miller and the baker more opportunities of dealing unfairly than if there were fewer kinds.

4118. *These various qualities are employed for different purposes. The best and whitest wheaten bread* ought to be made from the finest and whitest flour, called *firsts,* obtained from the first grinding.

4119. *Ordinary bread* is usually made from a mixture of firsts and seconds; but probably too often from a large proportion of the latter.

4120. *The best brown bread* is made of what is called *whole* meal, or *grist flour,* that is, meal or flour which has had only the bran taken from it, the pollard and the fine flour being ground up together. This flour can only be had by those who purchase their own wheat, and either grind it at home or send it to the mill. The expense of the latter is 1*s.* 6*d.* or 2*s.* per sack, and the bran is sent home as well as the flour; and one of the advantages of private or domestic grinding is, that the flour may be dressed in any manner that may be wished, without trusting to the miller. A bushel of wheat produces 60¾ lbs. of meal and bran, 1¾ lb. being lost in dust. A sack of wheat weighs 240 lbs.; and this produces from 178 to 190 lbs. of flour, together with from 40 to 45 lbs. of bran; some mix with the grist flour a little firsts or seconds. *For an inferior brown bread,* some mix one fifth of pollard with the grist flour; and the common brown bread of the farmhouses is made from country household flour, or wheat, of which the bran is retained in the meal, being ground down extremely fine. This bread is considered as possessing, for some constitutions, a laxative quality.

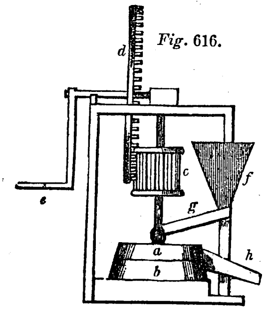
4121. *Domestic mills* are sometimes employed to grind corn, either in cases where a public mill is not accessible, or where it is wished to take certain means of preventing the possibility of any adulteration of the flour. Various contrivances have been made for this purpose; and it may be proper to state what they are capable of effecting in general.

The grinding of oats and barley is easy; and there is no difficulty in separating the husks from the meal by the sieve; but the grinding of wheat, and the separation of the flour into the different sorts, is much more difficult; and it is scarcely possible to effect this in a private family so perfectly as it is performed by the skilful miller.

Whether all the popular charges against the millers and bakers, of adulterating flour, are true or false, we do not take upon ourselves to determine; but the main object proposed by the use of domestic mills, namely, to secure an unadulterated material for bread, may unquestionably be obtained, although it will seldom be practicable to do much more than to separate the greatest part of the bran by the sieve, leaving a flour perfectly wholesome, but from which the best sort of brown bread only can be made. The proper grinding and dressing of wheat flour, with the view to obtain that of the whitest kind, will in general be found to fail for want of the necessary experience, which can only be expected from those who are millers by trade. Those domestic mills which act by means of stones are the best; but with the imperfect skill of those who will generally have to perform the operation of grinding, a considerable quantity of flour will always adhere to the bran, which will be lost; and with steel mills, which rather cut than rub down or grind the grain, the loss will be still greater. Upon the whole, therefore, little or nothing is to be expected on the score of economy by grinding at home; more particularly if, as probably will be found necessary, the labour is to be paid for, this not coming within the ordinary duties of domestic servants · nor should the inconvenience of the mill, and the noise it occasions, be left out of the account. Nevertheless, as we have stated, there are certain situations in which a portable mill is extremely valuable.

4122. *Domestic mills have been made nearly upon the same construction as the common corn-mill, fig.* 616, with this difference, that they are worked by the labour of two men, or a horse. We refer the reader to what has been already said on the action of the millstones in grinding. The two stones are seen at *a* and *b*. The upper stone is fixed upon a perpendicular axis called the spindle, and this has on it a trundle, *c*, the upper end of the axis, or spindle, moving in a cross piece. The trundle, and with it the stone, is driven by the cog-wheel *d*, which is worked by a winch, *e*, if the hand be employed. The corn to be ground is put into the funnel *f*, called the hopper, from which it falls into the shoe *g*, and thence into a hole in the top of the millstone, whence it gets between them and is crushed or ground; the meal flies out in all directions from between the two stones, but is stopped by the casing round the stones, and there it accumulates, falls out, and is conveyed away by the spout *h*. As the corn does not come out very readily from the hopper, the spindle is formed in such a manner as to give a slight knock or jerk to the shoe *g*, as it turns round, and this is communicated to the hopper. By a particular contrivance, the two stones can be placed closer or farther apart, for the purpose of grinding finer or coarser. Mills of this kind, where the power is sufficient, grind well; but the wearing away of the stones, and getting them new dressed, is a great inconvenience.

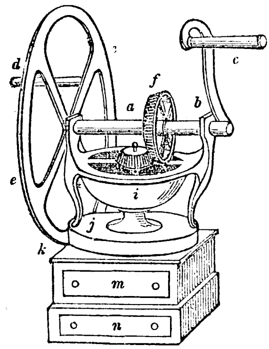
Fig. 616.



4123. *Some small hand-mills* resemble in construction those metallic coffee-grinders which are commonly sold in the shops. These consist interiorly of a solid frustum of a cone, the surface of which is cut spirally into furrows; this revolves within a hollow frustum of a cone a little larger, also furrowed; and the substance to be ground passes between these two. In the little box coffee-mills, the axes of the cones are vertical; but in the largest sort, fixed to the wall or a post, the axis and the cones are horizontal. This kind of mill is not well adapted to the grinding of corn, as they soon clog and make bad flour.

4124. *One of the best flour hand-mills of the latter kind* is that invented lately by Mr. Luke Herbert, and described in the "Mechanic's Magazine." It is made of iron, and not only grinds the corn, but, at the same time, dresses or sifts the meal into flour, pollard, bran, &c. *a*, *fig.* 617, is an axis turned by a winch, *c*, assisted, if required to be worked by two persons, by a handle, *d*, fixed to any one of the arms of the fly-wheel *e e*. The axis, *a*, also carries a bevelled wheel, *f*, which drives a pinion fixed upon a vertical spindle that revolves in the centre of a metallic hopper, *i*, and carries at its lower extremity the upper grinder; to the circumference of the latter are attached brushes that revolve together with it inside the circular case *j*, cast in one piece with the hopper *i*. The lower grinder is fixed in the centre of the flat top, *k*, of the pedestal; and around the lower grinder, in the same place as its upper surface, is a ring of fine wire-gauze, over the area of which the brushes sweep in their revolution, continually scattering every particle of the meal, as the same is constantly projected in minute quantities all around the circumference of the grinders on to the wire-work, causing the flour to fall through into the drawer *m*, below; while the bran and pollard, which cannot pass the wire gauze, are continually being freed from their adhering flour by the action of the brushes, until they are driven through an aperture at the outer circumference of the wire-gauze, on to an inclined screen of coarse wire-work, where the offal separates itself, in the mere act of falling, into pollard and bran, both of which deposite themselves into separate compartments made in the drawer *n*. At *b* is a screw for regulating the admission of the corn; and there is also a contrivance by which the mill can be made to grind finer or coarser for various seeds, as maize, pease, beans, rice, &c., or for crushing malt. This machine is portable, perfectly cleanly, and prevents dust and waste. It is made entirely of iron, and if required to be carried to distant parts of the globe, several spare grinding plates are sold with the mill, in case of any wearing out. Printed directions by the proprietor for using it are sent with the machine. If it be required to convert this into a simple mill for grinding substances that do not require sifting, this is easily done by withdrawing the wire-gauze. With domestic mills, a horse will, in general, grind one bushel an hour; and an average day's work for a man will be about two bushels. Considerable attention is necessary to grind well. The friction produced in the process always occasions a sensible degree of warmth in the meal: the cooler the meal comes from the stones, the better is the flour, and the lighter the bread made of such flour. Meal that has been overheated is technically said to be killed; and it will be more apt to become damp and mouldy, and to be attacked by insects; nor can it be so easily bolted.

Fig. 617.



4125. *Good wheat should look plump, feel heavy in the hand*, and be of a clear, transparent, amber colour; and when masticated some time in the mouth, a considerable portion of a thick, glutinous matter, which is the pure gluten, free from meal, should be left behind. Its taste should be sweetish; and the thinnest skinned yields the most and best flour. We have shown that the part of the grain which produces the finest flour is the heart, or centre. This flour ferments rapidly; but the flour, or meal, produced by that part of the grain immediately under the skin, being softer than the heart, is not so easily reduced to powder, is inferior, and ferments with yeast with difficulty.

SUBSECT. 4.—*Constituents of Wheat Flour, and its various Qualities.*

4126. The nature of bread-making, and particularly that of fermented bread, cannot be properly understood until we are acquainted with the chemical constitution of meal and flour. Wheat flour being the most important, we shall describe this first. If a handful of wheat flour be kneaded into a paste under water, the latter will become milky; and if the water be changed several times, and the kneading be continued long enough, the substance remaining in the hand will no longer tinge the water, and will be found to consist of a grayish, tough, elastic mass, very different from what it was at first; it will be very adhesive, and will draw out in some degree like India rubber. This substance is *gluten*, which has been described in Chap. VII., Sec. III.

4127. *The substance separated from the flour in the operation just mentioned*, and which whitens the water, is *starch*, as may be seen if the whole of the water be suffered to remain some time at rest, when the starch will subside to the bottom. *If the* clear water be poured off and evaporated by boiling, a very small quantity of a *gummy sugar* will remain in the bottom of the evaporating vessel. Starch, gluten, and sugar are, therefore, the principal constituents of wheat flour; and they exist on an average in good wheat in the following proportion, per 100 parts: starch, 68; gluten, 24; sugar, 5; vegetable albumen, 2.

4128. *Gluten is one of the most important principles in wheat flour*, and it is this chiefly which gives it so much superiority over every other substance for bread, as it forms an adhesive paste, and is one of the principles of fermentation. It is not found, except in very small quantity, in any other grain but wheat; and none of them, as barley, oats, or rye, can be made into good fermented bread, except some wheat flour be added: yet it is the starch of the flour, being in greatest quantity, that furnishes the largest proportion of nutritious matter. The gluten is comparatively in a very small quantity; but it is still more nutritious, containing nitrogen (as was shown Chap. VII., Sect. III.), an element constant in the animal kingdom, but rare in the vegetable; and hence gluten has been sometimes called the vegeto-animal principle. The greater the proportion of gluten, as Sir H. Davy has shown, the better is the quality, and the more nutritious the flour. Although starch be less nutritive than gluten, we cannot doubt of its great value as food, when we see how well people are supported upon potatoes alone, which contain abundance of starch, but no gluten. The sugar is in the smallest proportion, but it is important; the fermentation of bread is supposed to commence with this principle, since it is found that if the sugar be washed out of flour, it will not ferment.

Mr. Eldin, who wrote on baking some years ago, separated a pound avoirdupois of wheat into, bran, 3 oz.; starch, 10 oz.; gluten, $\frac{1}{2}$ oz.; sugar, $\frac{1}{8}$ oz.; and 2 oz. loss.

4129. *It is said that good bread cannot be made of flour that is quite new*, and that it is better to keep the flour for two or three months, or even a year; but keeping too long deteriorates it, and sometimes it gets together in lumps so hard that they must actually go to the mill to be ground over again. Such agglutinated flour, however, is not always unfit for bread; if mixed with new flour, it will make very good bread. The bakers generally mix new flour with some that is a year old.

4130. *Although good bread forms one of the most nutritious and wholesome kinds of food, yet bread made of bad flour is one of the worst.* There is little doubt but that many complaints, the origin and nature of which are studied in vain by the physician, might be traceable to the unwholesomeness of provisions, and that of bread among others. In this case, prevention is what we are to look to; cure is often beyond the power of medicine.

In describing rye, we mentioned the dreadful disease which *horned* or *spurred* rye is capable of generating, and that all grain was more or less liable to be infected in the same way. The existence of the diseases in corn called *blight*, *smut*, *mildew*, and *canker* has been long known to the farmer. Blights and mildews are owing to many causes, as cold, frosty winds, which nip and destroy the tender shoots of the young plants and impede their growth; but it has been ascertained that they are frequently caused by the growth of an extremely minute parasitic plant of the fungus tribe, the seeds of which are wafted in countless myriads through the atmosphere, and germinate in places favourable to their development. Smut, which infests wheat, barley, and oats, is one variety of these fungous vegetations; it appears in the form of a black, sooty powder, found in the ear, and more or less offensive to the smell; when examined by the magnifier, it appears as minute globules, each of which is a distinct plant. When this occurs, the farina is totally destroyed. If the injured ear be struck with the finger, the powder will be dispersed like a black smoke. These singular and destructive bodies have been studied by Mr. Bauer, and drawings of them are deposited in the British Museum. There are two varieties, called *Uredo segetum*, or smut, and *Uredo fetida*, or canker; the seeds are supposed to be taken up in the soil by the roots, and carried into the young plant by the sap. The canker is not seen on the exterior, but when the ears are bruised, they have a powerful and fetid odour, and are sometimes threshed along with the sound ears, rendering the whole unfit for food. The smut is more obvious, attacking not only the grain, but the stalks and leaves, which appear as if dusted over with charcoal. These plants are so minute, that Bauer has calculated that it would require 2,560,000 to cover a single square inch; and each of these contains 10,000,000 vegetating granules, or, as they are called by botanists, spores, which are the seeds; the multiplication must therefore be inconceivable. Washing the seed corn in water, particularly lime-water, previously to being sown, is the best preventive known. These diseases in the wheat have not only the effect of lessening or destroying altogether the farina of the grain, but render very unwholesome flour made from corn which has among it any infected grains.

4131. *The mouldiness which appears upon old flour*, or stale bread, is likewise a minute plant that grows upon such substances as are in a certain stage of decomposition. Flour or bread in this state is highly dangerous as food.

4132. *In all cases where corn has been subject to disease*, or the flour has been badly kept, it is the gluten that suffers most, being the part most liable to decomposition; and as we shall show that the raising of the bread depends upon the gluten being uninjured, it is obvious that good bread cannot be made from damaged flour; and though chemical means may be resorted to for assisting the fermentation, yet this can only deceive the public, and enable the bakers to make bread porous and apparently wholesome out of flour of very inferior quality. Instead, therefore, of showing how bread, passable in appearance, may be made out of bad flour, it appears to us much safer to point out the impropriety of using such flour for baking bread: it is best to reject it for this purpose, or employ it in some way where perfect condition is of less importance.

4133. *In wet seasons, corn*, but more particularly barley, from its rapid growth, is liable to sprout or germinate more or less, even in the grain; and it will sometimes throw out young green leaves while still in the ear. The consequence of this germination is, that the corn, when threshed, heats and ferments, and the starch of the grain becomes partially converted into saccharine matter; the grain, in fact, being in some degree malted while yet growing. When this is the case, the gluten as well as the starch is affected, and flour made of such grain will not ferment readily for bread. This germination of the grain can only be stopped by drying it either in a kiln or an oven.

4134. The loss of gluten almost entirely destroys the adhesive power of wheat flour, and it then forms only a sort of pap or soft matter, instead of presenting that consistency and elasticity which distinguish flour of good quality, and which are of such consequence in the making of wheaten bread, as will be shown when we treat of the fermenting of bread.

4135. *When flour is genuine, or of the best kind,* it holds together in a mass when squeezed by the hand, and shows the impressions of the fingers, and even of the marks of the skin, much longer than when it is bad or adulterated; and the dough made with it is very gluey, ductile, and elastic, easy to be kneaded, and which may be elongated, flattened, and drawn in every direction without breaking.

4136. *A method has been pointed out by M. Taddei, an Italian chemist, by which bad flour which has suffered from keeping may be detected.* The gluten which remains in the hand on kneading it in water consists of two principles, both of which are essential to good flour. If some of this gluten be digested in boiling alcohol, or even kneaded by the hand in alcohol, a part will be dissolved, which is the proper gluten, and has been named *gliadine;* what remains undissolved is the vegetable albumen, and has been named *zymome,* from a Greek word signifying ferment. If some of the latter, moistened, be rubbed in a mortar with powder of guaiacum, a beautiful greenish blue colour will appear after a few minutes. As this principle zymome is always present in good flour, the same colour, though less brilliant, will be produced when the flour itself is so treated with guaiacum; but with flour spoiled by keeping, and in which the gluten has suffered spontaneous decomposition, no colour, or very little, will be perceivable. This guaiacum may be made a test of the goodness of flour by the brightness of the colour produced.

4137. *Flour after being ground is put into sacks,* each sack containing five bushels, and weighing two hundred and eighty pounds; this will produce about three hundred and forty-seven pounds of bread.

4138. *The great corn market in London is the Corn Exchange* in Mark-lane, where, on Mondays and Fridays, samples of grain, tied up in small bags, are sent by farmers and corn-merchants, with a label on each, stating the numbers of quarters and the places where they are deposited. To this market the millers, mealmen, and corn-chandlers resort, and the business is transacted by brokers. In most of the country towns the corn is exposed in bulk by the farmer, by which the purchaser is better enabled to judge of the quality.

4139. *The price of flour* ought to be according to the price of wheat; but it is said to be often kept up in London by mismanagement or monopoly. It is considerably cheaper in many parts of the country than in the metropolis.

Subsect. 5.—*Yeast.*

4140. The nature of yeast, called also *barm* in the North, has been fully explained under "Fermentation," and again under "Brewing;" and it is sufficient here to remind the reader that it is the frothy substance that rises to the surface during the fermenting of malt liquors; it contains the fermenting principle, which is the cause of what is called the *rising* of the dough in making bread by the disengagement of carbonic acid gas. Yeast for baking is generally procured from the brewer, if there be one sufficiently near; but it must be from the brewing of ale; that from porter would prove too bitter. Yeast from home-brewed ale is generally excellent.

In large capitals, such as London and Edinburgh, yeast for baking is so much in demand, that it is prepared expressly for the use of the baker, and its manufacture becomes a separate trade. In large baking establishments the bakers prepare it themselves. It is of the first importance in the preparation of bread that the yeast should be of the best kind; and it should not be above twenty-four hours old. It may sometimes happen that yeast cannot be procured from a brewer, and that it is necessary to make it by some process.

The following is the general method; but some more particular receipts will be given in Section VIII.: Proceed with a small quantity of malt as if you were brewing beer; mash, boil with hops, and cool; then add some brewers' yeast to ferment with, and at the same time mix with the wort a quantity of flour. Fermentation will ensue, and a high head of yeast will be obtained; when this begins to fall, it is strained through a sieve, and is fit for use.

4141. *It sometimes happens that the yeast is found to make the bread too bitter.* When this is suspected to be the case, it may be deprived of its bitterness in the following manner: mix it with a considerable quantity of water, and set it by to rest for some hours, when the thickest part will subside to the bottom; pour off the water on the top, and use only the stiff yeast that has settled.

Yeast from the brewer is improved for the purpose of baking by being mixed up with three or four table-spoonfuls of bran to a pint of yeast; water is then added sufficient to make the dough, and the whole is strained through a sieve. The flour of the bran increases the fermentative power of the yeast; and if the latter be rather flat, it may be still farther assisted by using sweetwort to dilute it with instead of water. If no sweet-wort is at hand, a little may be easily prepared thus: Simmer gently over the fire for a quarter of an hour, three or four table-spoonfuls of ground malt in a pint and a half of water, adding a table-spoonful of brown sugar or honey; keep the mixture for a few hours on the hob, and then strain it.

Yeast, when kept for a few hours after skimming, shrinks into one fourth of the space which it occupied at first, and then it is called by bakers *solid yeast,* frequently mentioned in books on this subject. A sack of flour generally requires from three to four pints of solid yeast.

If yeast should happen to be a little sour, which it will sometimes, particularly in country places, there can be no harm in correcting this by carbonate of soda.

Subsect. 6.—*Water.*

4142. *Water in bread-making is made use of not merely to wet the flour*, but also to promote the chemical action of the various principles on each other, which in the dry state would remain passive.

4143. *The increase in the weight of bread* above that of the flour and the other solid ingredients employed is remarkable, and proves that a large portion of water has combined with the principles of the flour, chiefly with the starch; but a part of the water is expelled by the heat of the oven, and another portion is evaporated as the bread becomes stale. A large quantity, however, remains fixed, and we must suppose it to be in a state of chemical combination with other principles in the bread. One hundred weight of flour will make 144 lbs. of bread weighed immediately as it comes out of the oven, and if the flour be very good, 150 lbs.; but in thirty-six hours the same bread will only weigh 139 lbs. The better and older the flour, the more water it will absorb and retain; but fifteen pounds of good wheaten flour ought not to be made to absorb above ten pounds of water in dough, which will produce about twenty pounds of baked bread. In general, one fifth of the weight of bread consists of water and salt.

Subsect. 7.—*Salt.*

4144. *Salt is always used in bread-making*, not only on account of its flavour, to destroy the insipid raw taste of the flour, but it is thought to make the dough rise better.

Salt is used either by mixing it at first with the flour, or by dissolving it in the water. A sack of flour made into bread will require on an average five pounds of salt.

Subsect. 8.—*Assize of Bread.*

4145. Owing to the vast importance of this necessary of life, it has been thought proper in most countries to subject its manufacture to certain regulations. Ever since 1266, in the reign of Henry III., the price at which bread should be sold had been determined from time to time by the magistrates, according to the current price of corn, which was called *setting the assize.* But in 1815 this was abolished by the legislature in London and its environs, and though the power to set an assize in other parts of the country still subsists, it is seldom acted upon, and has fallen into comparative disuse. According to the assize acts, a sack of flour weighing 280 lbs. is supposed to be capable of being baked into eighty quartern loaves; one fifth of each loaf is supposed to consist of water and salt, and four fifths of flour. The number of loaves which may be produced from a sack of flour depends upon its quality; good flour requires more water than bad flour, and old than new; something depends also upon the management of the baker. Sometimes more loaves than eighty, even as far as eighty-six, may be made from a sack of flour, and sometimes the number will fall short of eighty. By the assize acts, bakers were restricted to bake only three kinds of bread, viz., *wheaten*, made of the finest flour; *standard wheaten*, of the whole flour mixed; and *household*, of the coarsest flour. The loaves are the peck loaf, weighing 17 lbs. 6 oz.; the half peck, weighing 8 lbs. 11 oz.; and the quartern, 4 lbs. 5½ oz. avoirdupois.

4146. *The following is an abstract of the last bread act* (5 and 6 William IV., c. 37), entitled "An Act to repeal the several Acts now in force relating to Bread to be sold out of the City of London and the Weekly Bills of Mortality; and for the more effectually preventing the Adulteration of Bread, Meal, and Flour." Bakers may make and sell bread made of wheat, barley, rye, oats, buckwheat, Indian corn, pease, beans, rice, or potatoes, or any of them, along with common salt, pure water, eggs, milk, barm, leaven, and mixed in any proportions they may choose. "Bread may be made of any size and weight. Bread to be sold by weight, and in no other manner (French rolls and fancy bread excepted). Bakers to use avoirdupois weight, of sixteen ounces to the pound, and no other. Penalty for using false weights, £5. Bakers delivering bread by cart, &c., to be provided with scales and weights. Bakers convicted of adulterating bread by using any other ingredient besides those above mentioned, are liable to a penalty of £10, and to have their names and abodes advertised in the newspapers. Penalty for adulterating flour, meal, &c., £20. Bread made of any other grain but wheat to be marked with the letter M. Magistrates and peace-officers, by warrant, may search bakers' premises, and seize and carry away adulterated bread and flour. Penalty for obstructing search, &c., £10. Ingredients for adulterating flour, meal, &c., being found on bakers' premises, subjects the offender to a penalty of £10, and the like sum for every subsequent offence. Offences occasioned by the wilful default of journeymen bakers subjects them to fine or imprisonment. Bakers not to bake bread or rolls on Sundays, or follow any part of their trade, except setting sponge for next day's baking; but bakings may be delivered to customers until half-past one o'clock, and not later, on Sundays, under the penalty of 20*s*. No baker, mealman, or miller to act as a magistrate under this act, under a penalty of £100. One half of each penalty to go to the informer (and 3*s* extra on Sundays for his expenses), and the other moiety to the overseer, or other parochial officer.

CHAPTER III.

THEORY OF BREAD-MAKING; THE VARIOUS KINDS OF BREAD, AND MANNER OF PREPARING THEM.

Sect. I.—UNFERMENTED BREAD.

4147. *Leaven* having been, as we have stated in our "History of Bread," *the original substance by which bread was fermented*, there were at first but two kinds of bread, *unleavened* and *leavened.* Hence the term unfermented was then synonymous with unleavened; at present this is not the case, as bread prepared with yeast is, strictly speaking, also unleavened. Among the Jews, however, the use of the name unleavened is restricted to bread not at all fermented, and this use of the term is not unusual with others.

4148. *When meal or flour and water are kneaded together*, they form a tenacious paste called dough, not easily digestible by the stomach. The action of fire produces a considerable change on the gluten, and likewise in the starch of the flour, rendering the compound more easy to masticate and digest. Forming meal produced from any kind of grain into cakes by moistening it with water, and toasting these before the fire or on the embers, on a hot plate, or baking it in an oven, were the first methods practised of making bread, and these modes are still used extensively in many parts of the world. Milk, butter, eggs, suet, and other substances are occasionally mixed with the flour and water, to make the bread lighter or more agreeable. Unfermented bread may be flaky, but is never porous or spongy.

4149. *The primitive mode of baking bread is still preserved* among the Arabs of the desert, who, as Niebuhr informs us, "lay cakes of dough in hot coals, covering them entirely with the ashes till the bread, in their opinion, is quite done, when they take them from the ashes and eat them warm; but they prefer baking them upon an iron plate, which they carry with them, as cleaner."

Portable ovens are frequent in Eastern countries, and form part of the furniture of travellers in that part of the world. St. Jerome describes an Eastern oven as a round vessel of brass, blackened on the outside by the surrounding fire, which heats it within.

4150. *The bread eaten by the Jews during the Passover* is unleavened; and this usage was introduced in commemoration of their hasty departure from Egypt, when, not having leisure to bake leavened bread, they took the dough before it was fermented, and "baked of it unleavened cakes."

4151. *Unleavened bread is much used*, not only in this kingdom, but in other countries, every kind of grain not affording meal capable of being fermented easily by itself. This is the case with the meal of barley, oats, and maize. The method of making bread of this kind is extremely simple, and has the advantage of requiring the least preparation; although this species of bread is not so light and easily digested by those who have lived long in an artificial state of society, and who are accustomed to very different food, yet a large proportion of robust, healthy peasantry in the northern parts of this island subsist upon it.

4152. *Barley Bread.*—This is much used in Scotland, particularly in the Highlands, as also in Wales, in Devonshire, and some other parts of England. The barley meal is made into bread by kneading it well with water and a little salt; it is then formed immediately either into thick or thin cakes, as may be required. When made stiff, and about three quarters of an inch thick, called *barley bannocks*, they are toasted or baked before a clear, hot fire, by being placed upon the edge, and when nearly done they require to be watched well that they may not burn. It was most likely this sort of cakes that our great Alfred was left to take care of when a goatherd, and the neglect of which brought on the chiding which he experienced. Very thin barley cakes, called *scons*, are much used in the Highlands, particularly at breakfast; they are made by baking them quickly on an iron plate, and, when well made, are much relished; they are generally eaten warm, with butter. Barley bread is also much used in Norway: in short, in those countries which are too cold for the cultivation of other kinds of grain.

4153. *Oat Bread.*—Oatmeal is much used in Scotland, Lancashire, and other northern counties of England, and also in Wales. The mode of forming it into bread is the same as that with barley meal. When made thick, this bread in Scotland is called *bannock*, the term *cakes* being there reserved for the thin sort, which are first baked upon a hot plate, or griddle, till they are stiff enough to stand upon their edges, and then they are toasted before a turf fire, made on the hearth, till they are crisp. In farm-houses they bake a considerable quantity at once, and keep them on a rack fixed to the ceiling: they may be kept for a long time if quite dry.

Perhaps the most ancient mode of using oatmeal in Britain, and which is still kept up in the northern parts of the island, is by making it into *pottage*, or *porridge:* this is stirring meal among boiling water or milk in a pot over the fire with a little salt, till it grows thick or sets. This dish is eaten with milk, butter, or ale. An ancient variety of it is called *brose*, which is made by roasting the oatmeal in a frying pan till it is a little brown, and pouring over it the liquor in which beef has been boiled.

4154. *Sowans* is a species of food little known in England, but much used in Scotland. It is prepared from the husk, or bran, from which the oatmeal has been sifted, much in the same way as starch is from wheat. The husk of the oats (called *sids*) is mixed with water, and suffered to remain until it sours a little. The whole is then thrown upon a sieve, and water passed through. By this all the fine starchy matter is carried down into a tub with water placed beneath, in which it subsides to the bottom; the sour liquor is decanted off, and the sediment, still moist, is put into a vessel for use. To prepare it for food, equal parts of sowans and water are boiled till they thicken into a gelatinous substance, which is very wholesome and nutritive, and when fresh is very agreeable; by keeping it acquires a degree of tartness, but which is still not unpleasant. It is much used as a light supper dish, and is eaten with milk, cream, or butter, sweetened or not with sugar.

4155. *It is a general idea in England that the use of oatmeal bread heats the blood*, and occasions cutaneous eruptions. With respect to the first of these opinions, Sir Humphrey Davy states (*Agric. Chem.*, 138) that he was informed by Sir Joseph Banks "that the Derbyshire miners, in winter, preferred oat cakes to wheaten bread, finding that this kind of nourishment enables them to support their strength and perform their labour better. In summer, they say, oat cakes heat them, and they then consume the finest wheaten bread they can procure." With respect to the supposed effects of oat cakes upon the skin, Mr. Loudon tells us (*Encyclo. of Ag.*) "that the labourers in Angus and Forfarth, who live almost entirely upon oatmeal, are as free from complaints of this kind as they are in other places; and that when these do occur, they are to be ascribed rather to want of cleanliness than to their food."

4156. *Bread of Oatmeal and Pease.*—In some parts of Lancashire, and also in Scotland, they mix oatmeal and pease-meal, and make bread of these in the following manner: A peck of oatmeal and another of pease-meal are mixed well together, by passing them through a sieve; and to these are added three or four ounces of salt; the whole is then kneaded into dough with warm water. The dough is next rolled out into thin cakes, or made into flat rolls, which are baked on a hot plate or in an oven.

4157. *Unfermented bread may be made from any other grain* by a similar process; but as they are not in common use among us, we need not mention them.

4158. *Biscuits* belong to the class of unfermented bread, and are, perhaps, the most wholesome of that class; in cases where fermented bread does not agree, they may be recommended; in many instances they are considered lighter, and less liable to create acidity and flatulence. The name is derived from the French *bis cuit*, "twice baked," because originally that was the mode of entirely depriving them of all moisture, to ensure their keeping; and although that process is no longer employed, the name is retained. The use of this kind of bread on land is pretty general, and some varieties are luxuries; but at sea biscuits are articles of the first necessity.

4159. *Sea, or ship's biscuits*, are made from wheat flour from which only the coarsest bran has been separated. The dough is made up as stiff as it can be worked, and is then formed into shapes and baked in an oven; after which they are exposed in lofts over the oven until perfectly dry, to prevent them from becoming mouldy when stored. One hundred and twelve pounds of flour produce one hundred and two pounds of dry biscuits. The method of preparing them for the use of the navy has long been admired for its simplicity and expedition; and lately, much adulteration having been detected by the contractors, the method has been still farther improved by the application of machinery employed by government. No salt is put into sea biscuits, that they may not attract moisture. The French sea biscuits are made with leaven; they are very brittle, and dissolve very easily.

But as these biscuits are never made in private families, it is unnecessary to describe the mode of their manufacture. A variety of biscuit, called *captain's biscuit*, is made in a similar manner, only of fine flour.

4160. *Abernethy biscuits*, so called from a town in Scotland where they were first made, have a little milk and some caraway seeds, and are more brittle than the last. Both these are now made by every biscuit baker. The mode of making other varieties of biscuits and cakes will be described under the heads of "Pastry" and "Confectionery," Book XV., Chap. I.

Sect. II.—THEORY OF THE FERMENTATION OF BREAD.

4161. *All kinds of meal and flour contain more or less of a peculiar substance* that ferments of itself; but a mixture of flour and water alone will enter into fermentation only very slowly. Four ounces of wheat flour with a pint of water, kept in a temperature of 70°, took four days before it began to ferment.

4162. *By the addition of either leaven or yeast to the dough, the whole mass is made to ferment more rapidly;* and, in consequence, a quantity of fixed air or carbonic acid gas is formed, as in the brewing of beer; but this air being in small quantity, and generated in the midst of the dough, which is very tenacious from the gluten it contains, does not readily escape, but collects in innumerable little vesicles or bubbles in the interior, which causes the dough to swell up and grow bulky, so that when it is cut across it appears to have numerous round cavities of various sizes, which had been filled with air. Baking stops the progress of this fermentation, by the drying up of the moisture that was necessary for its continuance; if permitted, it would go on to the acetous and putrefactive stages. When the bread is sufficiently baked, it retains its porous structure, the whole having a spongy appearance. The fermentation has also produced certain chemical changes in the dough, which render it more agreeable and lighter as food, and it no longer forms a tenacious mass.

4163. *What the chemical changes are, is far from being well understood;* but it is to be observed, that though raw flour contains starch, gluten, and saccharine matter, none of these substances can be found in their true character in baked bread; some chemical combination has therefore taken place, by which a new compound has been formed, and which is fitter for digestion than either of these proximate principles separately.

4164. *The chemical theory of the fermentation* which has been offered, and which is probably very near the truth, is as follows: The fermentative action in the dough is commenced by the saccharine matter and the gluten acting on each other, having been first excited by the yeast; and that the first fermentation is of the vinous kind, is proved by the production of alcohol in a small quantity, as will be afterward shown. The gluten and the sugar being diffused through the whole of the dough, the latter is rendered porous in the manner we have mentioned; and hence the impossibility of preparing bread which shall have those qualities from the farina of oats, barley, rye, or any of the esculent roots, in all of which the quantity of gluten is comparatively very small. During the baking, the starch, which was merely diffused through the mass while in the state of dough, combines, with a portion of water, into a stiff jelly, which renders the bread more digestible, and the gluten wholly disappears. Part of the water, at least, is chemically united to the flour, or fixed and rendered solid; thus increasing the weight of the bread, as has been already stated in p. 747.

That it is the saccharine matter which acts the principal part in the process of fermentation is evident, because, when this is exhausted, the vinous fermentation ceases; and if the fermentation be not checked by the baking, the acetous stage commences. It is also to the semi-transparency of the numerous thin partitions which divide these cells in bread, and which, in fact, constitute all its solidity, that its white colour is due. When bread of wheat flour is baked without being fermented, it forms a solid, dark-coloured, disagreeably-tasted mass, difficult of digestion; qualities which may be obviated by baking it into thin cakes rapidly on a hot iron plate; but these are not comparable to fermented bread.

Thus fermented bread has several advantages over unfermented. It is less compact, more agreeable to the taste, it loses its tenacious and glutinous qualities, and is more salutary and digestible. The cells render it more easy to be broken down in the stomach. It is a chemical compound, in which the gluten and starch have been altered, so as to be no more recognised and separable. It is also less liable to acescence.

4165. *It was at one time supposed that the fermentation of bread was of a peculiar kind, which was called the panary fermentation;* but it is now thought that this fermentation does not differ essentially from that of wine or beer, being only modified by circumstances.

The great objection to the identity of the panary with the vinous fermentation was that no alcohol had been procured from dough, though this might have been expected had the carbonic acid gas been the result of a fermentation of the vinous kind. This difficulty, however, has disappeared, and the question set at rest by an invention which has not only ascertained that alcohol is formed in dough, but by which it may be actually collected.

A company was even formed for obtaining the spirit generated during the fermentation of bread, and which, in the ordinary construction of bakehouses, is lost; but though spirit was obtained, the speculation failed to be profitable.

No doubt this first chemical change in the fermentation of dough is at the expense of the nutritive principles of the flour. It seems, then, to be a point to be attended to that, as soon as the advantage is obtained of having the bread raised, no time should be lost in putting a stop by the oven to the farther fermentation, in order to preserve that sweetness which renders bread agreeable; fermentation beyond that time, though it may produce alcohol, can only do so by decomposing the important principles of the bread; and the result of this will be to render the latter insipid, as well as somewhat less nutritious.

It was said that in the new process only such spirit was collected as formerly absolutely escaped notice, although it is always found in the mode employed by the ordinary baker, the bread losing nothing that it generally possesses; and it was farther said that this bread does not get sour by keeping. It is, no doubt, true that a small quantity of spirit is formed in the usual mode of baking, and which is lost, from there being no method of collecting it; but this quantity is extremely small, and probably not worth the trouble of attempting to preserve. On the contrary, by pushing the fermentation as far as it will go, the whole, or a very considerable portion of the saccharine principle is destroyed, and the bread suffers in its qualities.

4166. It has been remarked, that although sugar is the principal substance decomposed in consequence of the fermentation, yet about three per cent. is still found in bread baked in the usual manner, the flour having had only five per cent. But it is the stopping of the fermentation by the process of baking that has prevented the whole of the sugar from being decomposed, which would have happened had not this been done, or if the fermentation should proceed far enough. It is not improbable that some of the starch of the flour may have been converted into sugar during the baking.

4167. It must be observed, likewise, that this method of collecting alcohol in baking can only be practised in establishments on a very great scale, and adapted for the purpose, the apparatus being of a peculiar structure; it is therefore altogether inapplicable to domestic bread-making, and even to the business of the ordinary baker; and we have said so much, more to illustrate what had been called the panary fermentation than with any practical view.

4168. *There are two general modes of making fermented bread.* The most ancient method was by taking advantage of a spontaneous fermentation, which dough made from flour or meal undergoes when left to itself. The bread so produced is what is called *leavened bread;* and the origin of the name will easily appear from our account of the mode of its preparation. The other method, and that by which our ordinary wheaten bread is now always made, is the bringing on the fermentation of the dough *by the addition of yeast.* We shall first describe leavened bread, which will enable us best to perceive the advantages of the other method.

Sect. III.—Leavened Bread.

4169. *Fermenting bread by means of a leaven is an improvement upon the mere leaving a mass of dough to spontaneous fermentation,* as mentioned above. If dough were left to ferment by itself without any addition, the effect would be unequal, and would vary according to the proportion and condition of the several constituents of the flour. The saccharine part would be disposed to run into the vinous fermentation: the mucilage would have a tendency to become sour, while the gluten would soon verge towards the putrid state. These changes would proceed with greater or less rapidity, as the several parts were on the outside, and exposed to the atmosphere, or whether they were in the interior of the mass. Occasional mixture of the whole would cause these effects to be more uniform; but still, bread made in this manner would be imperfect.

4170. *The great improvement by leavening consists in this:* to produce the desired uniformity of fermentation, a piece of dough is kept in a warm place until it has undergone the fermentation just described; then, if this piece, now called a *leaven*, be well mixed up with a quantity of fresh dough, of which bread is to be made, it will communicate its fermentation to the whole mass, and every part will ferment with greater rapidity, equally, and at the same time, by which a uniformity will be produced that otherwise would not have happened.

4171. *Bread fermented by means of leaven is now rarely used in England, and is confined to rye bread*, or to a mixture of wheat and rye, called *meslin* in the north of England, where these two grains are sown together, and go through all the processes of reaping, threshing, and grinding in this mixed state. In some places of the north, oaten bread is occasionally fermented with leaven; yeast is said not to answer so well for it.

4172. *It is always customary to reserve as a leaven* for the next batch of bread, some of the dough, when it is just in the state fit to be baked; and it is only in case of this being neglected, or that leaven is not to be procured, that recourse is had to making an original fermentation. As it is now the custom for one person always to get leaven from another, it is probable that the original ferment in any country might have been produced centuries ago. In the north of England a pound or more of leaven for the next baking is kept fit for use for weeks, buried in a sack or cask of flour. In Italy it has been kept good in this manner for several months. The French keep it for a week in a warm place between two bowls, adding every day some flour and water; if they wish to keep it longer, they dry it by a gentle heat, and when it is wanted, rub it down to a paste with warm water.

4173. *The producing of new leaven is a tedious process*, and it does not always answer so well as what has been kept from a former baking, being apt to run into putrescence. It is made by working wheat flour with water into dough; this is kept in a temperature of from 70° to 80°: the time of its rising will vary considerably, from a few days to a fortnight. In this process the fermentation is at first of the vinous kind, as mentioned above; it passes, however, very soon into the acetous; and leaven is generally distinguished by a slight acidity, which it gives to the bread. If very skilfully managed, however, bread made in this way is sometimes not inferior to that which is fermented with yeast, and some persons prefer it.

Scarcely two centuries have passed since almost all the bread consumed by the labouring population in England was made of rye flour, either by itself or mixed with wheat. But though rye bread is now little used in Britain, it is still the only kind used among the peasantry in many parts of France, Germany, Norway, and other northern European countries, particularly in the sandy districts near the Baltic, where no other grain than rye can be cultivated. In Sweden it is universally used, wheaten bread being never seen except in the towns. They bake rye cakes only twice a year; and consequently these become at length almost as hard as wood.

4174. To make rye bread, mix wheat and rye flour together with water at a blood heat; add to half of this a small bit of leaven, and after kneading the whole together very well, leave the dough in a warm place, covered up with a woollen cloth. In a few hours or more the dough will rise; next knead up this fermented dough with the other half that was left, adding as much salt as is necessary. Leave this mass for a few hours to ferment farther and swell, and then make it up into loaves for the oven. The time required for baking, and the method of it, are the same as for "Yeast Bread," which see. It requires some experience to be able to determine the exact quantity of leaven necessary; if too little is used, the bread will be heavy; if too much leaven be employed, or if the dough be suffered to lie too long before baking, the bread will have a disagreeable sour taste. Some use milk instead of water to wet the dough. 100 lbs., consisting of equal parts of wheat and rye, will produce from 154 lbs. to 156 lbs. of leavened bread.

Since, with the exception of wheat, rye contains a greater proportion of gluten than any other corn, it is easy to be fermented, and is a strong, hearty, though coarse food.

4175. *Rye bread is also sometimes fermented with yeast*, and then it has not the acid which leavened bread generally has.

SECT. IV.—BREAD FERMENTED WITH YEAST, AND MADE BY PUBLIC BAKERS.

4176. Since it is difficult always to ferment leavened bread so as not to produce more of a sour taste than is agreeable, it was a great improvement to substitute yeast as a ferment, the bread so produced having no unpleasant flavour, and being, at the same time, lighter.

4177. *Method of making Bread by the London Bakers.*—The baker first sifts a sack of flour into the kneading trough; he then dissolves four or five pounds of salt in a pailful of hot water; and when this has cooled down to 84°, from three to four pints of yeast are added, blended well with the water, and passed through a sieve. A hole is now made in a heap consisting of one third of the sack of flour, and the whole gradually worked up in a small trough with the water he has prepared into the consistence of stiff batter, quite free from lumps. The surface of this is made level, some flour is sprinkled over, and it is covered over with sacks or cloths; this is called *setting the sponge.*

In this situation it is left for an hour or two; a fermentation takes place, carbonic acid is disengaged, which, had the mass been semi-liquid, would have risen to the surface in bubbles, that would have broken; but, from the viscidity of the dough, the air, though it forms cells, is confined, and the sponge swells to double its original size. If this was suffered to go on, the air would at last escape, and the sponge fall down. When the baker perceives that the process has advanced sufficiently far, he mixes with the sponge all the rest of his sack of flour, and incorporates the whole together by a laborious course of kneading for upward of an hour, and the mass is then called *dough*.

This setting the sponge is useful by way of precaution, in order to try how the yeast will act in raising the dough, without using up the whole quantity; as any necessary alteration can be more easily made in this stage of the process than after the whole of the flour is mixed up.

If the dough is too thin, the bubbles of gas would all escape, and the raising would subside; and if the baker were to suffer the fermentation to be completed before baking, the bread would pass into the sour state. The baker, therefore, does not carry on the fermentation all at once, but adds the sponge at twice or three times, and also the flour. The perfect kneading is essential, that the fermentation may be equal.

The dough is now left to itself for an hour and a half, with a little flour sprinkled all over it, and it is likewise covered with a woollen cloth; during this time the fermentation continues, and spreads through the whole mass. It is then subjected to a second but less laborious kneading, that the vesicular structure should be equally distributed. The dough is then cut into pieces, each being made, by weighing, of the proper size for loaves, and when shaped into proper forms for the oven, they are set aside in a warm place for some time. They are then put into the oven by a shovel for the purpose, and left in it about two hours and a half or three hours; when taken out, they are turned with their bottoms upward, to prevent them from splitting, and are covered up with a blanket to cool slowly. The loaves, when they come out of the oven, are about twice the size they were when they went in.

4178. *Kneading the dough in some places is performed by machinery*, which is certainly superior to the usual mode of employing the hands, and sometimes the feet of bakers. At Paris and Genoa, mechanism is occasionally employed; and at Geneva, it is said that the bakers are compelled by law to send their dough to be kneaded at a public mill constructed for that purpose. Various dough-making machines have been patented here, of which that by Hebert is one of the best. A kneading machine, simple, cheap, and requiring no art to use it, is employed by many French bakers; and it is desirable, for the sake of cleanliness, that it should be introduced here. It is figured in the "Dictionnaire Technologique."

4179. *Methods of raising the Dough without Fermentation.*—The chief advantage of the process of fermentation in making bread being the production of gas, which forms numerous cells that give that peculiar porous texture seen in the crumb of a loaf, any other process that will produce a similar texture will answer to make good bread. Accordingly, sub-carbonate or bi-carbonate of ammonia being mixed with the dough, the latter will, on baking, become spongy, as if it had been fermented with yeast. The reason is this: the carbonate of ammonia, being very volatile, is, by the heat, converted into a gaseous body, which, after filling the dough with cells, flies off entirely, leaving not a trace behind. This has been occasionally practised by London bakers.

4180. Another method is also used by some bakers, for which a patent has been taken, and the bread produced by it is called *patent unfermented bread*. Instead of the ordinary quantity of common salt put into the dough, carbonate of soda and muriatic acid, in due proportions, are kneaded up with the dough as rapidly as possible, which causes it to rise immediately. The explanation is this: the muriatic acid unites with the soda, and sets free the carbonic acid of the carbonate; this gas then distends the dough, giving it a vesicular character. The muriatic acid and soda, being the ingredients of which salt is formed, remains in the dough as salt, no other salt being necessary. This method is found to answer, and to make excellent bread; by it time and trouble are saved, and all risk of carrying the fermentation too far, as in the common method with yeast, is avoided. By some it is thought that bread made in this manner is particularly suited to invalids.

Sect. V.—Adulteration of Bread.

4181. There is no doubt that both flour and bread have been occasionally adulterated, and sometimes with deleterious substances, though, we believe, such practices are at present not common. It is, however, useful to know what are the substances usually resorted to for sophistication, and likewise how to detect such frauds.

4182. *Flour of bad or indifferent quality, or damaged*, being sold at an inferior price, is perhaps at present what we have most to dread from dishonest bakers, since the means of detecting deleterious substances introduced instead of flour are so simple and well understood, that few will venture to use them. The mere inferiority of flour cannot easily be discovered by chemical tests, and can only be judged of by the general quality of the bread.

It is chiefly to conceal the defects of the flour that alum, and sometimes sub-carbonate of ammonia, are added. When the flour is damaged, the gluten is in part destroyed, and it is difficult to make the bread rise sufficiently without the addition of something.

4183. *Alum has certainly been employed* by some London bakers for the purpose of adulterating bread, since many convictions have taken place of bakers who were found to have alum in their possession for this purpose. We believe, however, that there are many respectable bakers who never employ so deleterious a material. The following will be useful information, in order to put the public upon its guard:

There are several objects for which alum is put into bread: one of them is to enable the baker to make out of imperfect or damaged flour a bread that shall look as if it were made from the best flour; a second motive is, that the bread may absorb more water, and, therefore, weigh more than it ought from a certain quantity of flour; and a third is, to make the loaves part from each other more readily. The first two reasons are positively fraudulent; to the last there would be no objection were the alum perfectly harmless. It is well known that it is impossible to make the whitest kind of bread light and porous, and of the colour and appearance to which the public are now accustomed, of flour alone and unadulterated, except it be of the very best quality; and we have shown that when wheat flour is damaged by any cause that injures its gluten, the bread made from it will not rise properly. The way in which alum acts in covering this defect, as well as that of colour, or what may be termed bleaching the flour, is not well understood; but the fact appears to be, that a small quantity of alum is sufficient to produce a remarkable effect. It has been confidently asserted that many bakers purchase a mixture of flour, alum, and salt, for the purpose of adding it to damaged flour, and that this is known among themselves by the name of *sharp whites;* sometimes it is called *stuff*. By means of this compound, they are enabled to deceive the public, and to make bread composed of bad flour pass for that which can only be manufactured from pure ingredients. Dr. Ure states that he found the proportions of alum in bread to be variable, but that its quantity appeared to be in proportion to the badness of the flour.

4184. It has been said that the small quantity of alum which is employed (an ounce to a sack of flour) cannot be prejudicial to health; others maintain, that the proportion of alum, if used at all, is as much as three or four ounces to a sack of flour, and that less will not have the desired effect. On this subject, however, medical men generally agree that even a small quantity of this astringent substance taken continually cannot fail to injure the constitution. The practice is forbidden by law, and any tampering with the health of the public deserves severe punishment. It is pretty certain that alum is not used by the most respectable bakers; and it is quite certain, that when the best flour is employed, alum is not necessary to make the bread white.

4185. *To detect alum in bread* requires some knowledge of chemistry; and we must recollect that alum consists of sulphuric acid, alumina, and potash. Crumble about two ounces of the bread suspected in half a pint of distilled water; boil the mixture a few minutes, and filter the liquor through unsized paper. Evaporate the fluid to about one fourth of its original bulk; divide it into two parts. Into one of these let fall a solution of muriate of barytes (now called chloride of barium); if a *copious* white precipitate ensue, which does not disappear by the addition of pure nitric acid, the presence of alum may be suspected, as this precipitate indicates sulphuric acid. Into the other half drop a little aqua-ammonia; if alumina be present, the other constituent of alum, a light precipitate will appear, which will be re-dissolved by a few drops of a solution of caustic potash. Bread made without alum produces, when assayed in this manner, merely a very slight precipitate, which originates from a minute portion of sulphate of magnesia, contained in all common salt of commerce; and bread made with salt freed from sulphate of magnesia produces an infusion with water which does not become disturbed by the barytic test. There are more accurate methods than this, by detecting the several constituents of alum, sulphuric acid, alumina, and potash; but as these demand considerable acquaintance with the methods of chemical analysis, they can only be practised by persons conversant with that subject, who will readily find the means of accomplishing this object.

4186. *We have, in the last section, mentioned two methods* which are practised of raising dough without the usual process of fermentation; one by the use of carbonate of ammonia, and another by means of carbonate of soda and muriatic acid. By both of these methods carbonic acid gas is disengaged, which renders the bread porous and light; nor are they in any way hurtful to health, the ammonia, through its volatility, flying off entirely, and the salt formed by the last process being only common salt, such as is always used in bread. But it is to be observed that bakers can by these processes cause dough to rise made of flour spoiled, or, as they call it, *sour flour*, which could not be raised easily by yeast, and therefore bread may thus be made of bad flour to look nearly as well as if made of the best. Occasionally, however, these processes are employed for other purposes than those of sophistication; they are sometimes used with yeast to ensure the rising of the dough in cases of difficulty, or where the bakers are in a hurry.

4187. But although bread baked and raised by these means is vesicular or porous, and nearly similar in appearance to bread made with yeast, yet, when closely examined, the nature of its pores is very different; the pores are generally large, and the mass is seldom spongy, or full of minute pores, and frequently a large cavity is formed in the loaf; it is, besides, difficult to expel the last traces of the ammonia, which sometimes leave an unpleasant taste. Vogel has made some accurate experiments on this subject, and he has shown, in opposition to what has been asserted, that it is impossible to make such good bread by the use of water impregnated with carbonic acid gas, mixtures of carbonate of soda and tartaric acid, or any method of generating gas, as by the employment of yeast.

4188. *Some white substances are said to have been employed by millers and bakers for the purposes of whitening flour and bread* by direct mixture, as chalk, plaster of Paris, bones calcined and ground, which are all very prejudicial. It is very unlikely that these are now often used as adulterating ingredients, however they may have been, since the means of detection are so well known. If any such materials are suspected in bread, it will be sufficient, in order to discover them, to boil some of the bread in a certain quantity of water, when the substances will separate and fall to the bottom as a white powder, which may be examined by a chemist. It is scarcely necessary to say that no powder of this kind can be any part of the flour itself; but if any such occur, it must be the consequence of sophistication. If the powder be chalk, oil of vitriol (called also sulphuric acid and hydrochloric acid), diluted with six times its weight of water, will occasion an effervescence or bubbling when poured upon it.

4189. *The general preference that is given to bread very white has been considered to arise from prejudice*, and it has been said that it is in consequence of this false taste in the public that bakers have been, in some degree, compelled to seek out methods of making their bread as white as possible beyond what their profits will allow. It is very necessary that we should be extremely cautious how we admit of excuses for the adulteration of so important an article of food as bread, and it is highly desirable that we view the subject in its true light. We have already explained that the finest flour is composed of the central part of the grains of wheat, and, when the grain is of the best quality, this part is extremely white. The exterior part of the wheat affords a flour less white. The whiteness of flour, therefore, when it is pure and unadulterated, becomes in some degree a test of its having been produced from the centre of the grain, which gives what is called the finest and best flour. Good wheat likewise affords a flour whiter than damaged wheat, or than the meal of other grains, as barley, oats, pease, and beans. It is no wonder, therefore, that the public should have the impression that the whiteness of flour, and, of course, of the bread made from it, is more likely to be of the first quality rather than what is of a darker colour, since the latter may not only consist of inferior flour, but may be adulterated with some other substance. Bread of the whole of the wheat is, of course, much less white than what is made of fine flour, but it is said to be quite as nutritious, or even more so, and hence the preference of very white bread is called a false taste. But it does not appear to be clearly established that brown bread is more wholesome in general than white, if the latter be pure, and there is a reason why, weight for weight, the white is the most nutritious. The flour of which brown bread is made drinks up more water in making it into dough and baking than the white; hence, in an equal weight of white and brown bread, there is most water, and, of course, less nutritive matter in the former. It is true the brown is also the cheapest, but it is said that the labouring classes find the white, after all, the most satisfying, and therefore, as they suppose, the most economical. This may or may not be so; but if true, their preference of it cannot be called a prejudice, and white bread is more likely to be of good quality than what is worse coloured; for though substances are sometimes used to give artificial whiteness, yet these, being of so easy detection, are probably very seldom made such use of; and if there is no adulteration by the intermixture of other substances, the whitest bread is most likely to be the best, as it ferments most readily, and contains most gluten and starch.

4190. *The most general adulteration of bread, as it is made at present, is the mixing potatoes with the dough*, which has become so frequent a practice, that bakers make no secret of it. Many of them assert that good bread cannot be made without it, and that such bread is more light, palatable, and digestible than that which is manufactured from wheaten flour alone. We must confess that we doubt the truth of this statement in the way in which it is intended to be understood. The addition of potatoes to bread may serve the baker's purpose, since potatoes cost him less than an equal weight of flour; potatoes are not an unwholesome addition, and bread made in this manner may be very palatable; but when we consider the composition of wheat flour and of potatoes, the latter containing no gluten, which is the most nutritive part of wheat flour, it must be obvious that bread mixed with potatoes is less nutritious than an equal weight of what is made solely from wheat. Should this practice be admitted to be fair, and the price of such bread reduced in proportion to that of the ingredients, there might be no reason for complaint; but to put as large a quantity of potatoes into the bread as the flour will allow of, and then to charge as much for this bread as for bread all of wheat flour, is certainly an imposition. With respect to the addition of potatoes being any improvement in bread, it is extremely difficult to decide such a question except accurate experiments were made with the materials, and such experiments can scarcely be expected from the bakers. We have certainly seen bread of the very best quality made in private families without a particle of potato, and until the superiority of potato bread is distinctly proved, we must withhold our belief that it is an improvement upon that where the best flour and other materials are employed.

We are aware that the *flour*, or *starch*, of potatoes is largely manufactured in Paris for the pastry-cook, but this article is dearer than flour, and is therefore used for other purposes than adulteration. Our bakers do not use the starch or flour of the potato to mix with their dough, but rub up with it the whole of the potato, which contains but 30 per cent. of starch.
